Like the other organs of the apparatus of digestion, the large intestines may be deranged in different ways; they may be disordered from atony, from morbid irritability, from inflammation of their mucous membrane, from disorder of its follicles; all which morbid conditions afford the means of dividing colonic dyspepsia into a corresponding number of species.

I.—*Atonic colonic dyspepsia.*

Synonyms.—Obstipatio debiliū, *Cullen*; mimoses; acute disorder of the general health, *Marshall Hall*; celiacus affectus, *Celsus*; colica stercorea, *Etmuller*; colica flatulenta, *Sennertus*; lien verberans, *Bonetus*; stridulous affection of the bowels, *Bradley*;^{*} tenesmus à scybalis; dysodia stomachalis, *Sauvages*; excrementitious plethora, *Barlow*.

General character.—Bowels habitually confined, but alvine evacuations not remarkably altered; pain or uneasiness in some part of the colon, variable in degree, situation, and constancy; often stridulous noise in the abdomen.

Though costiveness is the leading symptom of this disease, it would be a mistake to suppose that it consisted in costiveness alone, or that constipation of the bowels was the only symptom which an atonic state of the colon gave rise to.

Form of disease.—This disease is not confined exclusively to either sex; it is most common in young females, and in delicate boys or young men. After there has existed for some time an habitually confined state of bowels, or a morbid state of them, in which, though evacuations occur daily, they are scanty and insufficient, the patient appears slowly and imperceptibly to fall out of health; but it is some time—several months, even years—before his ailments attract serious attention. The patient has no marked or distinct complaint, but the appetite is impaired, there is lassitude, loss of strength, weariness after any bodily exertion, a general, sometimes painful feeling of weakness, an aching over the whole body, or very distressing pains in the loins and lower extremities, attended with some degree of torpor, especially on walking or long standing; and hence the patient is constantly constrained to sit down or to rest on a sofa. There is frequent headach, great nervousness or susceptibility of impression, a tendency to perspiration on the least surprise or exertion, fluttering, faintishness, timidity, discomposure by the least hurry or agitation, sometimes tremor and vertigo. At first there is no loss of flesh, but the skin grows coarse, the countenance puffed and bloated, the complexion dull, foul,

and greasy, and the lower eyelid becomes dark, sallow, or otherwise discoloured. But as the disease continues, there is considerable loss of flesh; the complexion loses its colour and turns pale, sometimes dead-pale, sometimes swarthy pale, sometimes rather chlorotic; the countenance becomes thin, the features sharp, and the lips, more especially the upper lip, are sensibly paler than any other part of the face; the surface of the face is somewhat shining and glossy, or is frequently affected with a slight degree of clammy or oily perspiration, especially about the nose; and the orifices of the sebaceous follicles appear as small black points disseminated over the surface; and the discoloration under the eye increases to sallowness or a greenish black colour.

Pain is frequently complained of in some part of the colon, which, when it exists in an aggravated form, is various and irregular in its situation, course, degree, and duration; its approach is sometimes sudden, often slow and progressive; at first it is apt to change its situation from one side to the other, or from one part of the colon to another, and frequently appears to move up the chest or to the back, but by degrees it becomes more permanent in its situation; it is commonly observed in one of the iliac regions, frequently in the right iliac region in the course of the ascending colon, in which situation the pain on some occasions becomes very acute, aggravated by violent spasms returning in paroxysms, and not rarely attended by vomiting and great irritability of stomach, (the *colica stercorea* of some authors,) often the forerunner of stercoraceous tumours, and ultimately of that disease which has been described by Dupuytren under the name of phlegmonous tumours of the right iliac region, and which has been recently well described by Mr. Ferral.* A common situation of the pain is in the left side just under the false ribs, and very often in the left iliac region in the course of the sigmoid flexure of the colon; in this last situation it is occasionally attended with a frequent desire to go to stool, accompanied with distressing tenesmus. Frequent though ineffectual efforts are made to obtain a stool for several days, and at length a number of small hardened and slimy lumps, or scybala, either separately or connected together, similar to sheep's dung, more rarely of a flattened or tape-like form, will be voided, sometimes preceded and sometimes succeeded by liquid and sanious stools of various colours and of a frothy consistence, always extremely offensive. This is the *tenesmus à scybalis* of some authors, and the dysentery of others, of which inflammation and ultimately ulceration of the mucous membrane, and occasionally stricture of the lower part of the colon, are the remote consequences. On some occasions the pain and soreness is felt about the middle and lower part of the hypogastrium; and a slight pain is also experienced on micturition. Sometimes there may be per-

* Observations on a Stridulous Affection of the Bowels. London, 1818.

* Edin. Med. and Surgical Journal, 1831.

ceived in the course of the colon a distinct hardness or tumour, which appears to arise from a loaded state of the intestine; an occurrence particularly apt to take place in females, and more especially in the left iliac region. When the disease has made some progress, the hypogastrium is generally swollen, especially in the evening and fore-part of the night, but in the morning the enlargement has nearly or altogether vanished, in some cases leaving a degree of soreness in that region.

One of the most common and most distressing, as well as unpleasant attendants of this complaint is a disagreeable noise not unlike the croaking of a frog heard in the bowels, proceeding more especially from the left side. This noise is very much under the influence of respiration, and also any state of excitement. For the most part, especially on inspiration, it is similar to the croaking of a frog; but on expiration it is somewhat less so, conveying the idea of the sound issuing, as it were, from water; often before it ceases, it is like the plaintive sound of a dying animal. *Dicitur genere de turture, τέρζειν et τρούζειν.* At every act of inspiration, on laying the hand on the left umbilical region about two inches or two inches and a half from the navel in a transverse direction towards the spine of the ilium, a sensation is felt as if some liquid was forcibly spirted or dashed against the peritoneum; on expiration this is less perceptible. This curious verberation is not always confined to the same part of the abdomen, as it will often be found two and a half or three inches from the navel in the direction of the spleen. During its presence the patient seldom complains either of pain in the part or on any moderate pressure, or even from change of posture; but if the part be suddenly pushed by a moderate force, great pain is often felt in the region of the stomach, so much as to cause fainting, a circumstance which more particularly happens when the pulsation approaches the epigastrium. At first this stridulous noise returns at uncertain intervals in the course of the day, and is of no limited duration. The period of its continuance, however, seldom exceeds twenty minutes or half an hour; it is particularly marked whilst the patient is in an erect posture; on lying down it will almost instantly cease, and be no more heard as long as the body continues in an horizontal posture. Whatever is taken into the stomach, whilst the body is erect, has no inconsiderable influence in exciting or abating this stridulous sound. For instance, after the patient has sat down to a meal and taken a few mouthfuls, it will almost invariably ensue, and continue for some time, after which it becomes weaker, and intermits more and more till it ceases. In other cases, however, instead of food producing this effect, it oftener abates this noise, especially when the stomach is empty, and there is faintness and a sense of craving for food. In the advanced stage of the complaint, the noise frequently returns, even while the patient remains in the horizontal position. The varied state of the bowels seems to have

little influence either in augmenting or diminishing the noise in the abdomen.

If the state of the organic functions be inquired into, they will be found to betray a considerable deviation from the state of health. The appetite is generally impaired, sometimes to loathing, but frequently without any symptom of gastric or duodenal dyspepsia; sometimes there is a remarkable irritability of the stomach, the patient throwing up part of the little nourishment taken immediately on swallowing it; and this vomiting is often attended with pain or uneasiness in, or tightness across, the stomach; sometimes there is faintness with a sense of craving for food. The tongue always presents an unhealthy appearance, almost invariably it is loaded or covered with a white slimy fur; sometimes it will be found coated with a whitish fur, inclining to a yellowish tinge, and often dappled towards the root, especially of a morning; occasionally for a few days this incrustation is diminished, and the patient is more disposed for food, but this change is of short duration. Frequently the tongue is loaded, swollen, and œdematous, and marked by pressure against the contiguous teeth; it is frequently so large in proportion to the mouth, that from compression it is found more or less divided with sulci or folded into plaits. The teeth and mouth are foul; the gums also are frequently coated and palish; the inside of the cheeks, like the tongue, is often impressed by pressure against the teeth; a vitiated taste is sometimes perceived, particularly in the morning; the saliva is viscid, the breath tainted and fetid, sometimes emitting a heavy strong smell, not unlike roasted meat, sometimes a putrid, even stercoraceous odour. The bowels are at first always constipated, afterwards constipation and diarrhoea occasionally alternate; in advanced cases the latter state becomes permanent. The fæces at first exhibit in general no unnatural appearance, except that they are scanty and indurated; afterwards they are occasionally fluid, scanty, dark-coloured, and extremely fetid, often accompanied with mucus and even blood; sometimes, as already observed, they are attended with tenesmus, bloody stools, and pain in the right iliac region, an occurrence very common in young females. In the commencement the urine is high-coloured and apt to be loaded, depositing a whitish sediment, and presenting a supernatant iridescent pellicle; afterwards it lets fall a mucous deposit, sometimes of a lateritious tinge; during the continuance of the disease the urine frequently becomes limpid, but slight exasperations of the complaint restore the deposit. The pulse is frequently nearly natural; sometimes it is quick or easily accelerated, or variable, and apt to become irregular and intermitting; it is usually soft and weak, sometimes small; it varies in point of fulness, and continues to increase slowly in frequency as the complaint advances. The skin is in general cool, rather moist and clammy, particularly the hands and feet, which are apt to be obstinately cold; the fingers are rather livid, and the nails assume a lilac hue.

It is remarked by Dr. M. Hall, from whose exact portrait of this complaint we have drawn a considerable part of our description of it, that the condition of the countenance, the tongue, internal mouth, and general surface, is peculiarly constant and uniform in almost every case and every period of the disease, but that the other symptoms are characteristically inconstant and variable.

These symptoms are—an unaccountable sensation of weakness and weariness, the patient suffering from a sense of aching after slight exertion; a considerable loss of strength, sometimes amounting to faintishness in the upright posture, with a peculiar sense of fluttering at the heart and pit of the stomach; but the most frequent subjects of complaint are headach, vertigo, and nervousness. The headach, which is severe on rising from bed in the morning, inasmuch so as sometimes to excite vomiting, will continue unabated for an hour or two, and is often proportionate to the degree and length of time which the patient has slept. The patient is flurried by the least hurry, agitation, or excitement, is very frequently affected with nervous tremor on the least surprise or least exertion, frequently manifested in a quivering of the lip or dimpling of the chin on speaking, or, when at all agitated, by tremor on holding out the hand, or carrying a cup of tea to the mouth, on attempting to stand or walk, or on being fatigued or hurried. Sometimes there is oppression, heavy sleep, or considerable stupor or obtuseness of intellect during the day, and during the night great wakefulness and restlessness, disturbed sleep, dreams, and incubus.

The patient is liable to violent and sudden attacks, generally induced by some improper article of diet or a more than usually loaded state of the large intestines, such as sickness, vertigo, faintishness with cold perspirations, paleness of the countenance, and coldness of the extremities. These attacks are sometimes accompanied with spasmodic or convulsive paroxysms, frequently assuming the form of hysteria, more rarely of epilepsy, and occasionally temporary delirium, loss of memory, or absence of mind. Sometimes the attacks consist of spasmodic or anomalous pains about the heart or side, or in various parts of the abdomen; in fluttering, irregular action, violent palpitation of the heart, with syncope; in local pains more or less severe, occasionally so severe as to resemble *tic douloureux*, of longer or shorter duration, and in various forms and situations; in some cases resembling the passage of gallstones, in others inflammation of the pleura, of the liver, spleen, kidneys, and intestines or peritoneum, and affections of the bladder. Sometimes there is an extraordinary loss of muscular power, especially of the lower extremities, which are so enfeebled as to appear affected with paralysis.

Curvature of the spine is not a rare complication and consequence of this disease, more especially in scrofulous constitutions. Its approach is very gradual, and long before any deformity can be observed, on forcibly pressing with the fingers on each side of the spinous

processes of the third or fourth lumbar vertebra, considerable pain will generally be excited, inasmuch as occasionally to produce a degree of sickness. The seat of this pain is, however, confined to no exact point. After a considerable time the patient experiences a further increase of weakness and derangement of the general health, and the spine, at the place above mentioned, will now be found giving way, either slightly projecting anteriorly or to the left side. In consequence of the curvature of the spine to the left side, the right hip has the appearance of being enlarged, by reason of the hollowness between the iliac and vertebral column being increased, whilst the left hypogastric region is more swollen than the right.

Dr. Bradley conceives that the disease of the spine is the primary affection, of which the stridulous sound and other derangements are only the consequences. We confess that to us his reasoning presents a very remarkable instance of a false induction; for on his own admission there is no constancy of conjunction between the affection of the spine and the stridulous noise, as every practitioner must be able to confirm. They are both accidents of a more general disorder, only connected together through their common cause.

Causes.—A certain period of life from the age of ten to thirty seems very much to favour the formation of this disease. It may be partly connected with the natural conformation of the body and the development of the constitution at this particular time of life; but perhaps it is more strictly dependent upon the change of habits coincident with it in the children of the rich, who are either unremittingly occupied with their omnifarious education, or, to obtain a graceful carriage, steadfastly confined to one posture, the undeviating sedentariness of the body presenting a remarkable contrast to the desultory activity of the mind; and in the children of the poor, who are of necessity obliged to seek their bread in the sedentary occupations of needlework, in the tedious and wearisomeness of manufactories, at the tambour, the stocking or the lace-frame. Hence females, who are under boarding-school discipline, and rigidly subject to it, being compelled to sit many hours of the day with the head erect and the shoulders thrown forward, are liable to this disease; hence governesses, sempstresses, milliners, mantua-makers, students, and all persons of sedentary and inactive occupations, are the chief sufferers from it. The effect of sedentariness is increased by any causes which have a relaxing influence upon the body; and hence the confined or impure air of apartments, the warm relaxing vapoury air of some occupations, as that which arises from working over ironing-stoves, or from the steam-engines of manufactories. But every circumstance which tends in any way directly or indirectly to impede the evacuation of the bowels is the most influential cause of this complaint. Hence not lending a ready obedience to the calls of nature, which often arises in children from indolence of habit, but more frequently from being placed in situations where their modesty checks them

in doing so, and, at a later period of life, from the unbending restraint and thralldom of society; or amid the fatigue, care, and anxiety of life, from neglecting a due attention to the state of the body.

Pathology.—The explanation of the nature of this disease presents no difficulty. That it consists in a state of atony and insensibility of the colon, the most probable consequence of habitual over-distention of its muscular fibres, there seems to be little reason to doubt. The symptoms may be clearly and distinctly traced to this morbid condition of the colon, with which also it seems easy to connect the disorder of the general health which ensues. For, sometimes by continuity, sometimes by sympathy, deranging the function of gastric and duodenal digestion, sometimes by defective excretion changing the state of the circulating fluid and interfering with the process of nutrition, sometimes by the sympathetic irritation of distention disturbing the functions of the nervous system, and by pressure impeding the circulation in the abdomen, (from which cause and continuity, the functions of the womb and pelvic viscera become disordered, and the spine loses the support of the antagonist muscles,) it seems all-sufficient for the effects which we attribute to it.

When the disorder of the colon is secondary, supervening upon gastric or duodenal dyspepsia, it appears to be merely a degree of languor or sluggishness in the bowel causing delay in the passage of its contents, the consequence of the bile and other secretions being less adapted to support its action; but when its contents are longer delayed than usual, they become hardened, and irritate the surface of the intestine, causing tenderness on pressure, a feeling of hardness in the part, and all the symptoms of colonic disorder already described.

Treatment.—The indications for directing the method of cure are, *a.* to remove any accumulation of feces by having the bowels fully and satisfactorily evacuated; *b.* to facilitate and promote the regular performance of the function of the colon; and, *c.* to correct the morbid condition of the colon, the proximate cause of the disease.

a. For fulfilling this indication purgatives cannot be dispensed with; but though constipation is a constant attendant of this disease, they are not to be given with an unsparing hand. Rhubarb, combined with sal polychrest and a little ginger, the pulvis scammoniae comp. followed at a proper interval, if necessary, by a little infusion of senna, are the best description of purgatives. If the bowels are not easily acted upon, it is a bad practice to continue throwing in without discrimination any description of purgatives without allowing sufficient time for moderate doses to act. Mercurials are unnecessary unless the alvine evacuation does not resume its proper colour by means of the other class of aperients.

b. This indication may be fulfilled by the daily use of the warm-water lavement, and, if necessary, by some mild aperient medicines, just suffi-

cient to solicit the bowels without irritating them. The object should be to induce a full and consistent evacuation daily, avoiding as much as possible the fretting and painful operation of medicines by which the bowels are irritated. On the other hand, the power of the aperient must not be less than equal to obtaining a complete evacuation of the bowels; scanty evacuations will not suffice. Whilst, therefore, too considerable and too often repeated doses of medicines are to be guarded against, ineffectual medicines are equally to be avoided. Good forms of aperients are the pulv. aloes comp., decoct. aloes comp., or baume de vie in pimento water; a pill composed of equal parts of ext. colocynth. comp. and extract. hyoscyami: three, four, or five grains of this composition may be occasionally taken. The following formula affords a useful pill:—
R. pulv. aloes, pulv. gambog. saponis, ext. hyoscyami $\bar{a}\bar{a}$ 3 i. fiant pilulæ xx. Una vel duæ horâ somni sum.

Though the use of the warm-water injections in the loaded state of the bowels is frequently attended with pain in the course of the colon, or though they may not be at first successful, yet a perseverance in their use generally overcomes these obstacles and occasionally restores the natural and spontaneous action of the bowels: by preventing the constant distention by accumulated feces, the opportunity is afforded the intestine of resuming its tone and sensibility. But whether clysmata or aperients are used for relieving the bowels, opportunity should be from time to time afforded for their natural action, by leaving off, or gradually diminishing, the medicines.

The diet should be mild, light, and nutritious, taken in moderate quantities and frequently, not less than three or four small meals daily, for the frequency of the meal appears to have a considerable effect in promoting the action of the bowels. It should consist of mild animal food, boiled or roasted, and should be well masticated; mutton, chicken, beef less frequently; stale pure bread untoasted, mealy potatoes mashed, tea or coffee in moderate quantities. We have not known much advantage from using more aperient kinds of food, as fruits, figs, medlars, stewed plumbs, stewed apples, brown bread, oatmeal porridge, and such-like. They generally disorder the first processes of digestion.

The function of the bowels will be also promoted by a system of regular walking exercise, apportioned to the strength; but violent efforts and fatigue are injurious. Sometimes easy, lounging exercise, with complete relaxation of mind, has considerable effect in promoting the evacuation of the bowels.

c. The means of fulfilling this indication are partly direct, partly indirect.

1. When the bowels have been preserved in a soluble state, the use of tonics or chalybeates may be advisable for correcting the morbid condition of the bowels. When chalybeates have a tendency to keep the bowels open without causing griping, they are often of great

service, and we have had frequent opportunities of observing the superiority of the chalybeate mineral waters in this respect over the official chalybeates. But the state of the tongue must always be the guide for administering tonics, for as long as this is considerably furred, the most effectual means for removing such fur will prove the best tonic, and the utility of any tonic may be estimated by the return of appetite; therefore any stomachic tonic which does not effect its purpose by removing the fur is injurious.

Friction over the bowels with the flannel glove or flesh-brush, the galvanic circuit passed through the bowels and daily repeated, and in obstinate cases an occasional blister, are also direct means having the same effect in different degrees. But of all external means we have known the greatest service from the warm or cold douche upon the abdomen, continued for a month or six weeks, as so commonly practised in Italy.

2. The indirect means are sea-bathing, sponging the body with salt water or vinegar and water cold; change of air; country air; travelling; warm clothing; preserving the feet dry; relaxation from study, occupation, and business.

II.—*Inflammatory colonic dyspepsia.*

Synonyms.—Κοιλιακή, *Græcorum*; ventriculosa passio, *Cæl. Aurel.*; enteritis colica, colica phlogistica, *Sauvages*.

General character.—Pain in some part of the colon, prevailing most in one particular point, felt always more before an evacuation of the bowels, seldom increased on pressure; stools generally liquid, rarely formed, not always more frequent than natural.

Form of disease.—We wish, without encroaching upon the subject of diarrhoea or dysentery, to characterise by this term a disorder of the function of excretion arising from chronic or sub-acute inflammation of the colon. This complaint is manifested by pain in some part of the colon and by sense of extreme weakness or of fainting after an evacuation of the bowels. The patient is always remarkably lowered, irritated, or made otherwise uncomfortable by the action of purgative medicine, and even by the spontaneous action of the bowels, which is always followed by more or less feeling of exhaustion; he feels always most strong and most comfortable when his bowels are confined. Sometimes the pain or uneasiness extends over the whole abdomen, and there is also a certain degree of tenderness and an increased heat of the part; but more commonly the pain is referred to particular points of the colon, to which it is more or less confined—frequently to the caput cæcum coli and the ascending colon; sometimes to the arch of the colon; in young women to the sigmoid flexure. The pains of the colon are accompanied with a pulse somewhat accelerated and rather tense; there is some degree of thirst, but seldom much heat of surface. The motions present an unhealthy appearance; they are seldom formed, more commonly liquid or

pultaceous; sometimes they are light-coloured, almost white, sometimes yellow and frothy, less frequently green or black; sometimes a tenacious puriform matter streaked with blood is discharged, which on some occasions alternates with healthy feculent matter, and at other times is mixed with it; the evacuations are always fetid in some degree, on some occasions most remarkably so. They are generally more frequent than natural, but often they are not so, an evacuation sometimes not occurring oftener than once in two days. The stools are frequently discharged with considerable force, but occasionally there is tenesmus without any excrementitious discharge. The appetite is seldom much impaired. The complexion is pale or whitish, sometimes of a remarkable greenish paleness, and the body emits more or less of a cadaverous smell.

The unfavourable progress of this disease is to hectic fever accompanied with œdema of the lower limbs and face, dejected features, and gradual exhaustion.

Causes.—This complaint is a common consequence of the preceding form of dyspepsia, more frequently of the medicines which have been improperly used for its cure; the effect of distention from remora of fæces, or of harsh drastic medicines. It is also on some occasions produced by the irritation of worms, and may arise from accidental colds.

Pathology.—The nature of this disease has been verified by repeated dissections, which have shewn it to consist in various degrees of inflammation of the mucous membrane of the colon, sometimes very limited in extent, frequently terminating in ulceration, occasionally in thickening or induration.

Treatment.—Leeches or cupping to the painful parts used with caution and moderation; fomentations; covering the abdomen with a flannel roller moderately tight; light, bland, pultaceous diet; milk, if it is easily digested, or asses' milk; rest of body, sometimes confinement to bed or the recumbent posture, afford the only means of relief in this complaint.

III.—*Irritable colonic dyspepsia.*

Synonyms.—'Ερεγγυαλγία τοῦ στοῦ, *Hipp.*; colica hypochondriaca, hysterica, *Sydenham*; flatulencia hypochondriaca, hysterica, *Juncker*; flatulencia convulsiva, *Sennertus*; hypochondriasis tympanitica, *And.*; colique nerveuse; enteralgie, *French*.

General character.—Intestinal digestion accompanied with pain, uneasiness in some part of the abdomen, seldom fixed to one spot, but changing its situation, and intermitting.

Form of disease.—There exists a certain morbid condition of the intestines referable only to irritability or morbid sensibility, without either proof or sign of an inflammatory state of the mucous membranes. It is certainly most frequently met with in persons of irritable and nervous temperaments, and is therefore probably a consequence of that constitutional state; but the symptoms shew that

this morbid condition is sometimes pre-eminently developed in the intestines, in which the patient is sometimes the subject of the most painful, distressing, and unnatural sensations. It is always attended with hypochondriasis, a constant watchfulness and attention to all bodily sensations, which depress and overwhelm the mind. These patients frequently complain of pain, or of a sensation of twisting at the umbilicus or in the course of the colon; occasionally of acute pain in the same situation, seldom augmented, generally relieved, by pressure; frequently a sensation of sinking or dragging of the bowels, giving the notion of the intestines falling out; some patients experience this uneasy feeling to such a degree that they are obliged to confine themselves to the recumbent posture. Sometimes, instead of pain, the patient feels in the intestines an indescribable uneasiness or peculiar sensation similar to those which are perceived in the stomach in irritable gastric dyspepsia; occasionally the pain and preternatural sensation exist together, frequently they alternate with each other.

Frequently the chief subject of complaint in this disease is flatulence, which is generally accompanied with inodorous eructations, neither acid nor putrid, with stridulous noise in the bowels, borborygmi, with colic and spasmodic pains affecting different parts of the bowels, which are sometimes accompanied with pyalism and copious discharges of limpid urine.

A very aggravated form of this complaint has been described under the term *flatulencia convulsiva*. It occurs in men, and has a strong affinity to the hysterical passion of females, the sexual organs being strongly affected. Early in our medical career we witnessed a case of this disease, the paroxysm of which a more experienced and now justly eminent physician arrested by the application of cold to the testicles.

The uneasy feelings in this disease return or are exasperated during the intestinal digestion, which is ordinarily difficult and laborious. They are frequently dissipated by travelling or agreeable occupation of the mind, and return with repose. They are sometimes, however, aggravated by the least motion, and are excited by a fit of passion, by anxiety of mind, by any disquietude, sometimes by the least effort of attention. The pains and colic often supervene upon stormy or unsettled weather. We recollect to have seen a case of this disease which co-existed with a remarkably painful sensibility of the retina.

Under these complaints the patient may preserve the appearance of health, and though the function of digestion is painful, it is yet satisfactorily performed, the nutrition being little affected, and the stools healthy, though the bowels are generally disposed to be confined.

Every form of this complaint is most obstinate, and rendered doubly so by the mutable and variable state of mind of the patient, who

is contented with no method of treatment, and is every day changing his physician. He has not patience to wait for the operation of any medicine, but is unceasingly fretting his body with every description of medicine, particularly with aperients, by which his complaints are invariably aggravated.

Pathology.—Concerning the nature of this disease we refer to our pathology of irritable gastric dyspepsia. Bonetus gives the case of a person who had this complaint, marked by great pain and rolling of the bowels, attended with a moaning sibilous noise, for three years, in consequence of plum-stones lodging in the colon.

Treatment.—The cure of this disease, always difficult to be obtained, is to be sought for by a mild bland diet, easy of digestion. If milk diet agrees, the patient should confine himself to it. He should avoid any thing heating and irritating, and should shun every form of medicine as much as possible. The bowels are to be kept soluble by the easiest means. The patient should live much in the open air, and take exercise, chiefly on horseback. Sailing, and even long sea voyages are very useful. Of direct medicines we can speak most in favour of chalybeates, and the other metallic tonics. We have known the Kesselbrunnen of Ems of considerable service, but the worst case we have known was most benefited by the artificial Pymont water.

IV.—*Follicular colonic dyspepsia.*

Synonyms.—Colica pituitosa;* scelotyrbe pituitosa;† chlorosis pituitosa;‡ diarrhæa pituitosa,§ *Auct. Var.*; arthritis chlorotica,|| *Sauvages*; paraplexia rheumatica, *Id.*; infarctus,¶ *Kämpf*; colique glaireuse, *French*.

General character.—Pain, spasm, or uneasiness in the course of the colon, with the evacuation of considerable quantities of mucus in various morbid states.

Form of disease.—In persons of sedentary habits, more frequently young persons, and most especially young females who are generally subject to costiveness and accumulation of feces in the large intestines, the mucous follicles of those organs are liable to be disordered in the way we have already explained in the section on *follicular duodenal dyspepsia*, much to the aggravation and obstinacy of the other symptoms. Like that complaint, the present disease is most usually met with in cold phlegmatic habits, and its progress is insidious. After habitual costiveness and the establishment of that state of general disorder of the health which we have already considered under *atonic colonic dyspepsia*, the patient becomes subject to acute attacks of pain or spasm in some part of the large intestines, frequently amounting

† *Percy* winger.

‡ *Sauvages*.

§ *Id.*

|| *Musgrave*.

¶ *Etmuller*, p. 440.

to regular paroxysms of colic. The pain is occasionally confined to one particular part of the colon, frequently the ascending colon and the sigmoid flexure. Relief of these pains is only obtained by copious discharges of mucus in some of the various morbid forms already described. Etmuller has observed that the pain in this species of colic is more confined to one part of the abdomen, and conveys the feeling of a perforating or transfixing pain. But instead of this direct symptom of disorder, it is not unusual for the patient to be seized with a violent nervous affection. Children are frequently seized with convulsions, to which succeed chorea, and sometimes paralysis of the limbs. Young women in this complaint are often affected with hysteria, which may, however, be distinguished from the idiopathic form of that disease by the great variety of ways in which it attacks the patient, sometimes as catalepsy, at other times as imbecility of mind, neuralgic affections of the heart, convulsive asthma, loss of voice, loss of speech; it very frequently leaves paralysis of some member, most commonly of the lower limbs, differing from ordinary paralysis in the sensation of the limb being seldom impaired. Painful affections of the heart, violent headach, extreme restlessness and agitation, rheumatic gout, severe pain in some part of the spine, frequently at the bottom, may be enumerated amongst the secondary affections of this disease. In women the uterine functions are always painfully performed; and it is not unusual to see a metastasis of the function to other organs, to the lungs, appearing as hemoptysis; to the stomach, as hematemesia; to the bowels, as melæna. These derangements of the natural functions are various. Generally the patient becomes pale and delicate-looking, but sometimes preserves a natural appearance, or even good looks; the skin is cool, moist, and clammy, particularly the extremities; the lips and gums are pale, and the tongue is invariably large, moist, and covered with a thin clammy coating; frequently it is swollen and œdematous, divided laterally or transversely by deep cuts or fissures, and retaining the impressions of the teeth. The bowels are always constipated, often obstinately so, the most violent medicines having little effect; but when they do act, the stools are found to be abundant, gruelly, and light-coloured, frequently deficient of their natural smell, or having a faint muskish smell, and, if mixed with water, leaving a greyish calcareous deposit: sometimes they are extremely fetid. Occasionally the stools are mixed with shreds of membranous substance, or with mucus in various morbid states and forms, frequently in perfect tubes, some of which have been observed full half a yard in length; an appearance which has not rarely imposed upon the ignorant the belief that a portion of the intestines has been actually discharged. The urine is extremely variable, being sometimes scanty and loaded, almost deficient, at other times copious and limpid like water. The pulse, except under the excite-

ment of any violent attack, is always weak, small, and soft, generally slow; the circulation seems hardly to arrive at the system of the capillary vessels.

Pathology.—Under *follicular duodenal dyspepsia* we have already sufficiently inquired into the nature of the morbid condition of the mucous membranes which constitutes the proximate cause of this disease; a condition in which their surfaces are deprived both of their secreting and absorbing function as well as of their natural sensibility, their vessels losing their permeability, and becoming, as it were, impacted and blocked up with viscid or concrete mucus—*emphragma mucosum*. This state is the consequence of the membranes either from atony or inflammation losing the power of throwing off the mucus from their surface, and which, either accumulating or concreting in the follicles, gives rise to considerable tumours there; or, collecting, forms itself into the various forms of excreted matters already noticed. This unhealthy state of the mucous membranes, the consequence of a depraved function of secretion, is the proximate cause of many painful, even dangerous diseases, arising as well from the disordered function of the membrane as from the irritation of such unnatural substances in the alimentary canal, inducing different symptoms corresponding with the different situations they may occupy. The most common cause of this state is the habitual costiveness of sedentary persons, or the repeated irritation of the alimentary canal by crude and indigestible articles of food; but we have known it to be produced quite independently of these by the long-continued use of laxative medicines, and these by no means of the most irritating kind.

Treatment.—For the general treatment of this complaint we must refer to the corresponding form of duodenal dyspepsia. We have only to observe that, as a purgative for evacuating these *infarctus*, we have found the oleum terebinthinæ superior to any other.

IV. GASTRO-ENTERIC DYSPEPSIA.

The disorder affecting the function of more than one organ of the apparatus of digestion.

The preceding orders present dyspepsia in the simplest forms in which it is capable of existing, either such as it has been observed to assume, or to which it may be reduced by a careful classification of its causes, its symptoms, and its remedies. It is, however, neither pretended nor meant to be understood that it is met with always in these definite forms. In diseases there is nothing absolutely definite. They are not like animals or plants, each of which, nature, to preserve the integrity of the species, has surrounded with a distinct barrier. In strictness of language, diseases may be described, but cannot be defined. They pass so gradually into one another, that all the pathologist can hope to attain is to mark their leading and most constant phenomena. In describing the different forms under which dyspepsia presents itself, this is all that we have

either sought or professed to do; and though we are too well aware that not only the species or forms of the different orders, but that even the species of the same order, may be complicated with each other, we venture to assert that, however intimately the different species may be combined together, it is seldom that one will not be found predominating. A knowledge, therefore, of the elementary forms of dyspepsia gives the physician a most commanding advantage even in cases the most complex; enables him to decompose and unravel their complications; furnishes him with indications which, as it were, throw daylight upon his operation, simplify and assure his method of procedure, and afford him the means, if not of foreseeing, most certainly of early desecring, the effect of his remedies.

The characters which we have assigned to the different species of dyspepsia, are the result to which we have been conducted by the review of many cases in which the disease has been presented in its most simple as well as its most complicated forms, comparing the circumstances of one case with those of another, separating the constant from the contingent, referring each to the morbid condition with which it was found to be most constantly conjoined. And if any persons should be disposed to regard these morbid conditions as mere figments, or to regard the terms which represent them as mere empty words, we trust they will be reasonable enough to recollect that the name does not change the thing, and that if it serves to mark the constancy of conjunction of a group of phenomena, it matters not which word or what sign we may use for the purpose.

Were time or space allowed us, it would be the object of the present section to indicate and describe the complications of the different forms of dyspepsia, to trace the law of their combinations, and the order in which they co-exist or succeed each other;—circumstances well deserving the attention of the physician. But this task we must reserve for another occasion, and content ourselves at present with merely indicating some of the more common complications. We leave the full consideration of this part of the subject with the less reluctance, because we are convinced that a moderate attention to the elementary forms of this disease will render a description of their complications almost superfluous.

When the disorder of the function of digestion extends to the whole or to more than one organ of the apparatus—to the stomach as well as the intestines, the morbid condition may be the same throughout, or it may be dissimilar, thus giving rise to the division of *gastro-enteric dyspepsia* into what may be termed *enopathic* and *polypathic*.

The species of the first division must be necessarily limited, and determined by the morbid conditions which the organs are liable to assume. Hence they will be the four following:—

1. Atonic gastro-enteric dyspepsia.
2. Inflammatory gastro-enteric dyspepsia.
3. Irritable gastro-enteric dyspepsia.
4. Follicular gastro-enteric dyspepsia.

Even in these species it will seldom be found that the morbid condition exists in an equal degree in every organ of the apparatus; but, on the contrary, that it usually preponderates more in one than the other, thus approaching to some of the elementary species.

The second division admits of a much greater variety of species, co-extensive with the combinations into which the four morbid conditions are capable of entering. The following are those most frequently observed:—

5. *Atonic gastric with inflammatory duodenal dyspepsia*.—It is the constant tendency of long-continued dyspepsia of any form, whether it be atonic, irritable, or inflammatory, to localise itself, to attach itself to one part of the alimentary canal, which in consequence becomes the seat of morbid sensibility, morbid irritability, or of some modification of vitality, or of inflammation or some other modification of its vascularity. Dr. Wilson Philip has observed that in atonic gastric dyspepsia this occurs most frequently at the pylorus or upper part of the duodenum. Hence one of the most common forms of complicated dyspepsia is the species above indicated. It is deserving of remark that this localisation of the disease, this disposition to confine itself to one point, sometimes removes, frequently relieves, the original disease.

6. *Irritable gastric with inflammatory duodenal dyspepsia*.—This, also, is the consequence of the tendency just indicated, after irritable gastric dyspepsia has existed for a considerable time, or when it has been treated by heating or irritating remedies. It is met with commonly in persons of anxious, energetic, enthusiastic dispositions, in persons worn out and exhausted with cares, as for instance, in over-anxious mothers. The tongue is generally clean, small, and tremulous; its anterior edge of a smooth, glossy, light red colour; more rarely it is of deep red colour; or it presents a loose velvety appearance, like red plush; the lips are red, and there is a frothy saliva in the mouth. The patient complains of an uneasy gnawing sensation, a sense of fainting or sinking at the pit of the stomach; sometimes there is a constant excruciating pain in that situation. The uneasy feelings are much increased by medicines; they invariably irritate, produce discomfort, or disturb the digestion. The pulse is generally quick, wiry, and small, the skin dry and harsh, particularly the palms of the hand, which are rough; the urine is alternately pale and sedimentous.

7. *Inflammatory gastric with atonic colonic dyspepsia*.—This is a complication common in young scrofulous subjects, male as well as female.

8. *Irritable gastric with atonic colonic dyspepsia*.—Vomiting, more especially after meals, is the most leading symptom of this complication. It appears to arise from pressure of the loaded colon upon the stomach.

Of the complications of the different morbid conditions in the same organ of the apparatus of digestion, we must also reserve the consideration for another opportunity.

The only apology we have to offer for having occupied so large a share of the time and attention of the reader, is the importance properly attached to the disease which is the subject of the present article; for if considered in its almost universal prevalence and in its remote consequences, it is the source of more suffering to man than any other to which by his physical nature he is exposed, and, therefore, ought to precede all others in its claims upon the attention of the physician. It is, indeed, a very egregious mistake to imagine that this opinion, which attributes health to a pure digestion, and every species of disease to its disorders, is one of recent growth. It is one which has been sanctioned by the experience of the greatest physicians of every age and country. To the greatest of them all the healthy state of the function of digestion seemed so important, that he has not hesitated to declare, if not exactly in so many words, certainly in equivalent terms, that he who shall have discovered the means of a healthy digestion (which he considered to consist in the exact adjustment of food and labour,) shall have discovered the great secret of health: *ἢν μὲν γὰρ ἦν εὐεστὸν ἐπὶ ταυτοῖς, πρὸς ἑκάστην φύσιν, σίτου μέτρον, καὶ πόσιν ἀειθμὴς, μὴ ἔχον ὑπερβολὴν, μήτε ἐπὶ τὸ πλεόν, μήτε ἐπὶ τὸ ἔλαστον, εὖροιο ἀν' ὑγίει τοῖσιν ἀνθρώποισιν ἀκριβὴς.** In this respect Aretæus has gone a step beyond the father of physic; for to a healthy digestion he not only attributes health of body, but also health of mind: *στόμαχος ἡδονῆς καὶ ἀνδρείας ἡγαλμῶν καρδίας καλοῖον γειτόνευμα, ἐς τόνον καὶ θυμὸν ἡ ἀθυμίαν, τῆς ψυχῆς συμπαθεῖν ἥδε στομάχου πρῶτιστα δύναμις.†* And to give this opinion only its full extent, we may add with all propriety, that sweetness of temper, clearness of intellect, vigour of understanding, correctness of judgment, firmness of character, power of self-control, are preserved by a healthy state of the digestive organs, and may be lost by their disorder; for as it is by the diseases of these organs that intemperance works its mischief, all that sages, all that philosophers have delivered in praise of the virtue of temperance, may, without stretching a point, be fairly predicated of the healthy state of the function of digestion. When will legislators stoop to consider, or when shall legislators be made to comprehend, the influence of physical causes upon moral conduct?

The state of the digestive organs has the greatest influence upon the state of the other organs of the body. Their disorders are frequently the cause, frequently the consequence, of the disorders of other organs. "Sur dix cas de maladies aiguës," says one of the most distinguished pathologists of the present day, "qui ont leur point de départ ailleurs que dans le tube digestif, il en est huit à-peu-près dans lesquelles on observe un dérangement plus ou moins prononcé, soit dans la texture, soit dans les fonctions du canal intestinal. Dans les maladies chroniques, quelle qu'en

soit la nature, il est infiniment rare que le tube digestif ne subisse pas quelque alteration."* A similar opinion had been expressed by Cullen: "I am of opinion that we cannot bestow too much pains on the consideration of the affections of the stomach, as we find that, next to the pyrexia, they are the most frequent occurrences in practice." From these statements we might learn, did we not all already know, that there is scarcely a disease which afflicts the human body that can be correctly treated if the nature of the diseases of the digestive organs be not properly understood; and we may infer how much the difficulty of their treatment is increased, when, as Aretæus observes, the means which restore the health and recruit the strength in other diseases, are noxious in these: *ἡ ἐν τοῖς ἀλλοιοσι πάθει, μετὰ τὴν θεραπείην δάιντα ἐς ἰσχὺν καὶ κράτος τοῦ σώματος εὐπεψία ἀγαθή· στομαχομοῖσι δὲ μόνους ἥδε γίνεται πωλημελής.†* A thorough knowledge of dyspepsia in all its forms and varieties may therefore justly be considered the key to the cure of many acute and of most chronic diseases.

The mischief which springs from the disorders of the function of digestion is not limited to the individual—it extends to the offspring; for the disposition to these diseases being hereditary and increasing in virulence as it descends, the dyspepsia of one generation becomes scrofula, consumption, or some other malignant disease in the succeeding ones; hence the decay and extinction of families, and all the manifold attendant miseries. When will parents, besides, if not before, wealth and honours, think of bequeathing health to their children?

Moreover, as the diseases of the function of digestion may be said to belong peculiarly, if not exclusively, to a state of civilization, following it as closely as the body is followed by its shadow, they may be considered as the physical process by which luxury and refinement work the deterioration of the species, and prepare its decay—the under-current, which, setting against, stays or frustrates the progress of society. When will the physical state of the body cease to be deemed an unworthy means of promoting our moral—our religious improvement?

(T. J. Todd.)

INDURATION, (*induratio*, from *indurare*, to become hard.) This term is employed to designate an increase in the natural consistence of organs, in contradistinction to that of *softening*, which is used to denote the opposite state, or a diminution of the same property.

GENERAL PATHOLOGY OF INDURATION.

I. *Physiological modifications of consistence.*—In order to form an accurate estimate of the modifications which take place in the consistence of tissues or organs in a state of disease, it is essentially necessary to possess an accurate knowledge of the degree of con-

* De diætâ, lib. i. sect. 3.

† De causis et signis diuturn. morb. lib. ii.

* Andral, Anatom. Patholog.

† De curatione diuturn. morb. lib. ii.

sistence which these tissues or organs respectively possess in the normal state, as well as of the remarkable modifications which this property manifests not only in the different periods of life, but also during the progressive development of animal organization. The changes of consistence which are observed to take place under these different circumstances, although sometimes great in degree and extent, are nevertheless to be regarded as physiological conditions, and which mark in a particular manner the intermediate stages and extremes of life. Thus, when the phenomena of organization are about to manifest themselves in the impregnated ovum, nothing is discovered but a colourless liquid; organs when first perceived in the embryo are a mere jelly; and during their development, and in proportion as they approach to the perfect state, do they acquire a gradual increase of consistence. This progressive increase of consistence keeps pace with their development, and does not acquire that degree which belongs to each tissue or organ in particular, until it has arrived at a perfect state of formation. Now, we cannot but perceive here that the degrees of consistence must serve some important end; that even the almost fluid state of parts is not to be looked upon as a mere consequence either of an entire want or of an imperfect state of organization, but that it is a condition of organs or of the materials of which they are composed, subservient—if we may so speak—to the elementary acts of life; a condition which facilitates the transitions of form which organs must present before they can attain their more permanent and perfect state. By means of this condition of organs, whether transitory or permanent, nutritive elements subservient to growth and development find a nidus fitted for their reception, and fluids every facility for passing in whatever direction they are wanted; organs are moulded to the forms of the parts destined to receive and protect them; and numerous relations of bulk, position, situation, &c. are reciprocally adjusted between the containing and contained parts, as the changes which they undergo may render it necessary, in order to maintain the integrity and secure the well-being of each.

At the different periods of life, infancy, manhood, and old age, the consistence of the various tissues of the body, and consequently of organs, present great variety. In the first they are soft, spongy, largely embued with fluids, easily torn or broken; in the second, firm, more compact; the fluids are less abundant, and the solids resist considerable efforts to tear or break them. In the last period, the proportion of fluids is still less, and the solids have arrived at their maximum of density and cohesion.

The consistence of organs varies likewise according to sex, constitution, and the various conditions of life in which the individual has been placed. The difference of consistence arising out of these states is, however, by no means equally marked in all, and least as

regards sex, if we except the cutaneous and muscular systems, which, in the female, are more delicate and softer than in the male. Those states of the body which are connected with the predominance of the lymphatic system are characterized by a soft, flabby feel, the opposite of that which accompanies what is called a sanguineous temperament; and as an instance of the modifications of consistence which organs undergo in individuals submitted to the influence of external causes, we may refer to such as are the result of climate and various modes and conditions of life. The modifications of consistence, however, which depend on sex, constitution, or conditions of life, are, perhaps, never so great as to be confounded with those which constitute morbid states of this property of organs. It is far otherwise in the different periods of life; a degree of softness or induration equal to that which characterizes even the extremes of certain pathological states, constituting the peculiar character of certain parts at the periods to which we allude. Thus, the brain of the new-born infant, the mucous membrane, and even the muscles of organic life, are so soft as to be ruptured or broken down into a pulp by a slight degree of pressure or traction, just as we find to be the case in softening of these parts from disease, in after life. On the other hand, in advanced life, the cellular tissue; membranes, particularly serous and fibrous; the muscles and tendons; bone; the brain and nervous system; and particularly the uterus and ovaries, sometimes acquire a degree of hardness equal to that which is known to be produced by certain diseases, and which, by some pathologists, has even been described as a state of scirrhus of these organs.

It may not be unimportant to observe here, that numerous modifications of consistence similar to those which take place in man at the different periods of life, are found to exist in certain parts of some kinds of animals. In them, however, it is a primary condition necessary for the accomplishment of important functions, and, generally speaking, in no way dependent on changes induced by subsequent development, as in man. The conditions to which we allude consist in an increase of consistence or a positive conversion of one tissue into another of a similar but denser kind; a change necessary to enable the animal to live in a manner suited to its wants and the place which it holds in nature. Thus, in some animals, the cellular tissue, instead of being soft, spongy, and highly extensible, is naturally firm, dense, and fibrous; the epithelium an opaque, thick covering; the sclerotic a cartilaginous or osseous case; the epidermis, a horny envelope, &c. &c. The analogous changes which take place in man constitute pathological states, and not only subvert but entirely destroy the properties and functions of the organ in which they are accidentally produced.

If the physiological changes in the consistence of organs which we have noticed are

properly understood and applied, they will serve to explain many of the pathological changes which occur in man, whether we consider these in relation to the causes by which they are produced, the phenomena which accompany them, or the effects to which they give rise. These varieties in the physiological consistence of similar tissues in different animals show likewise, that when they occur as pathological states, they are in all probability subjected to the influence of the same general laws as the former; that the limits which separate the two states, that is, of health and disease, can be defined only by a reference to a change of structure or function as regards the particular tissue, system, or organ, in which it occurs, the age, sex, or kind of animal in which it is observed. Hence, in our examination of this, as well as of every other modification which takes place in the internal and external conformation and composition of organs, the necessity of taking as the point of comparison that state of each which is found to prevail at any particular period of life, and which constitutes the type of the condition whose changes we wish to describe.

II. *Pathological modifications of consistence.*—We have already observed that the opposite changes of consistence of organs are named softening and induration. The latter only will be examined in the present article.

A greater or less increase in the consistence of organs, particularly of the softer ones, has always attracted the attention of the pathologist, and whether existing alone or in connexion with other changes, has sometimes enabled him to determine the particular nature of a disease, more frequently to detect diseases at their commencement, even when no alteration of the bulk, form, colour, sensibility, or temperature of the part, was perceptible. Hence the importance which has long been attached to this physical alteration, but which, as regards its diagnostic value, may be fairly considered as having seldom served any higher purpose than a signal of alarm of present or of future danger. It is only within these few years that induration and inferior degrees of this state have been more successfully studied, and the knowledge thus obtained more usefully applied as a means of diagnosis. Several diseases, indeed, which were believed to consist simply in an augmentation of cohesion, in an increase of density of the solid materials of a tissue, are now known to depend on very different states; that a morbid increase of consistence is much more frequently dependent on the presence of an accidental or new product, fluid or solid, external to or combined with the tissue which is so altered, and consequently, that it is in these cases merely an effect, and no index whatever of the nature of the disease on which it depends. Mechanical, microscopical, and chemical analysis have shown that this physical condition varies much in its nature in the same or different tissues; and observation and experiment have also shown that it is produced by causes of a very op-

posite kind, and that the modifications of function by which it is accompanied are no less diversified. Since, therefore, induration is, in general, to be regarded as a symptom of previous or co-existing diseased states, it would appear to us to be of great and essential importance to determine, before proceeding farther, what the diseased states are on which induration depends.

Every degree and form of induration may be referred to changes which take place in the conformation and composition of organs.*

1. *Induration depending on changes which take place in the conformation of organs.*—The only change comprehended under this head, which gives rise to induration, is that of bulk.

Under change of bulk we include hypertrophy and atrophy, and changes in the quantity of the fluids of nutrition and secretion, as conditions which are not unfrequently accompanied with an increase of consistence of the otherwise natural and healthy texture of organs. Hypertrophy, however, is the only state in which increase of consistence can be regarded as a simple disease, inasmuch as it does not depend on the presence of a foreign product; the increased consistence in such a case being a consequence of a superabundant, molecular deposit of nutritive matter of a homogeneous kind in a tissue; and arranged in the normal order. But, that an increase of consistence depending on these circumstances should follow, it is not necessary that it should be accompanied by any change of bulk of the organ in which it is observed; for there may be hypertrophy without change of bulk, from the mode in which the additional deposit takes place.

The most remarkable examples of morbid increase of consistence depending on an augmentation in the quantity of healthy, solid material which enters into the composition of organs, are met with in those which are naturally soft; as in the medullary and cortical substance of the brain and spinal marrow; in the lymphatic and salivary glands, and in the cellular and muscular tissues, and even in those tissues which are naturally firm and hard, as the fibrous and osseous, in which the induration is sometimes extreme. The brain has not unfrequently been found increased to twice and even thrice its natural consistence; that of glandular, cellular, fibrous, and muscular tissues, become so hard, that they occasion a particular grating sound when cut; and the walls of some hollow organs, naturally soft and flaccid, acquire such a degree of firmness, that they preserve, when empty, a globular or cylindrical form, and spring up with considerable force after sudden pressure; and parts of bones acquire that degree of hardness which has been called eburneoid or ivory-like induration.

Induration, as a consequence of a diminu-

* We employ this arrangement here, having adopted it as the basis of our classification of all organic diseases.

tion in the quantity of the healthy solid material of an organ, is, perhaps, never observed, unless it is accompanied by other morbid states. It is only observed in soft, spongy, hollow organs, from which the fluids of nutrition have been removed, and for this reason we shall give examples of it under the following head.

Changes in the quantity of the fluids of nutrition frequently give rise to induration analogous to that which we have just now generally noticed, the one depending on an augmentation of the healthy solid, the other of the healthy fluid materials of an organ. The accumulation of blood in the vessels of the lungs, in the spleen, and tumours of a similar structure in various forms of congestion, produces sometimes a great degree of tension, hardness, and density of these organs.

Great diminution in the quantity of the same fluid is also followed by an increase of consistence of organs. Like the former, it is chiefly observed in the lungs and spleen, which feel as hard as liver or even cartilage. It is, however, to be observed that the increase of consistence in this case does not follow as an immediate consequence of the removal of the fluids of nutrition of these organs, but depends on the subsequent collapse and approximation of the walls of their vascular and cellular textures. In order, therefore, that induration of this kind should be great or permanent, it is necessary that there should be, besides the primitive cause, (*viz.*, the removal of the fluids,) an external or compressing force. Hence it is that induration of the lungs, of this kind, is met with most frequently in pleurisy; the lung may simply be compressed by the effused fluid, as in the acute form of this disease, or it may in addition be permanently enclosed in a dense fibrous membrane of new formation, as in chronic pleurisy. When a lung in this state is examined, it is found to be indurated merely from the approximation of its solid textures, and may be made to assume by inflation its natural bulk and consistence when the accidental fibrous envelope has been removed from its external surface. The constricting force of such pseudo-membranes is, perhaps, no where so marked and so peculiar in its effects as when it covers a portion only of a lung or of a single lobe. When a whole lung is contracted, reduced to the bulk of the fist, pushed into the hollow summit of the chest, or flattened and fixed along the spine by a dense fibrous covering, the effused fluid is generally believed to be the sole cause of the diminution of bulk of the organ and of its subsequent condensation. Such, however, is not the fact. It is also owing to that very remarkable property possessed by accidental fibrous membranes, by means of which they contract during the last period of their organization, and thereby gradually compress, diminish in bulk or capacity, or entirely obliterate hollow organs. It is, as we have already observed, when pleurisy has been circumscribed, limited to a single lobe or a portion only of one, that the effects of the

contractile property of the fibrous membrane are most strikingly illustrated. The portion of lung included in this membrane feels quite solid, hangs pendulous, or projects outwards in the form of a small tongue or dog's ear; or it may have a conical or cylindrical form of various dimensions. The portion of lung so compressed and indurated is immediately recognized not only from its diminution of bulk and peculiarity of form, but by the pale, uniform, white colour of its accidental fibrous covering, instead of the mottled aspect of the lung under the transparent pleura; and the cause of its density is farther demonstrated from the absence of every external compressing cause, fluid or solid (for it is not necessary that effusion should be present in such cases), except the fibrous membrane, and from its bulk and consistence being restored in the manner already noticed.

Condensation and induration of the spleen is often effected in the same way, that is, from the constricting force of an accidental fibrous membrane.

The last form of induration which we shall mention here, produced by the fluid contents of organs, is that which is found to accompany an augmentation in quantity of the healthy fluids of secretion: as of the milk in the breasts, semen in the testes, bile and urine in their respective reservoirs. The inordinate accumulation of any of these secretions in their proper vessels gives rise to a degree of hardness sometimes equal to that of hard tumours,—a circumstance arising from the incompressibility of the fluids themselves, and the state of condensation of the walls of the organs in which they are accumulated.

2. *Induration depending on changes which take place in the composition of organs.*—The increase of consistence included under this head may be referred to the presence of accidental or new products. These may be either fluid or solid. Of the first kind we have the natural fluids of nutrition and secretion, and some anomalous fluid products; of the second, we have all the solid accidental and new products which are found in the different textures and organs of the body. By far the greater number of these products require only to be named in this place, inasmuch as the induration which they produce depends on the degree of consistence which they themselves possess, and not on any change induced in the texture of the organ in which they are formed. There are, however, others, some of the natural fluids, and various anomalous fluid products, which, when effused into natural or accidental cavities, occasion from their accumulation, or the rapidity with which they are effused, great increase of consistence of the containing solids. When blood, or serosity containing various proportions of albumen and fibrine, is effused into the cellular tissue or the cavities of organs, the distention which these fluids occasion is sometimes so great as to render parts naturally soft and flaccid, quite dense, and almost unyielding. Thus the parenchyma of organs and the cellular tissue in general, when they be-

come the seat of hemorrhage, as pulmonary apoplexy, ecchymosis, &c. feel sometimes quite hard; and such is the state of the walls of the abdomen from the great accumulation of serosity in ascites, and of the cellular tissue of the extremities in œdema. The effusion of serosity into the intermuscular cellular tissue produces sometimes an extreme degree of induration, even when the muscular organ is not submitted to the influence of any external compressing cause. This is particularly observed in œdema of the tongue, in which this organ becomes as hard as a piece of wood. The same state is met with in the heart, although in a much less degree; also in the brain, liver, salivary and lymphatic glands. What is called hepatization of the lungs is a modification of consistence of a similar kind, but is produced by the presence of coagulable lymph, pus, and blood, as well as serosity.

To complete the general view of the diseases from which induration may arise, we have only to add that the accumulation of gases in the cavity of the abdomen and digestive organs sometimes occasions an extreme degree of tension and hardness of the abdominal parietes, and that collections of pus, atheromatous, melicerous, and other adventitious products, constitute swellings which communicate to the surrounding parts various degrees of induration. We may also note in this place, as a cause of induration, the accumulation of the contents of the stomach and intestines so frequently produced in these organs, particularly from stricture. Thus fecal matter may be accumulated in the cæcum, and communicate to the hand the sensation of a hard tumour in that region; or the whole of the colon may be similarly distended from stricture of the rectum, and be seen as well as felt throughout its whole course of an enormous size and extremely hard; and the stomach may be so distended in stricture or obstruction of the pylorus as to occupy the greater part of the cavity of the abdomen in the form of a globular swelling, offering considerable resistance to pressure.

Although the state of induration which we have been considering has always been confined by pathologists to changes directly or indirectly induced in the solids, whereby their consistence is increased, we do not see any reason why the same alteration, when considered in a general point of view, and as implying merely a modification of consistence, should not embrace changes of a similar kind which take place in the fluids of nutrition and secretion. The various degrees of fluidity which these products are found to possess, appear, in fact, to present us with some of the most simple forms under which the various degrees of consistence of matter can be subjected to our senses, at least in so far as regards the materials of organic composition. Various degrees of fluidity of the blood are observed, from a watery thinness to a state of inspissation approaching to coagulation, which last is, perhaps, a manifestation in an extreme degree of one and the same property. It is, indeed,

highly probable that the consistence of the blood depends principally on the fibrine which it contains, and may vary in degree with the quantity and quality of this important constituent,—an opinion, the truth of which appears to be proved by the fact that coagulation of the blood is no other than spontaneous solidification of the fibrine. The opposite state, or extreme fluidity produced by frequent hemorrhage or bloodletting, reduces this fluid to the consistence of serosity, chiefly by the removal of the greater part of its fibrine, —a further evidence of the influence which fibrine exercises on the consistence of the blood.

The consistence of the blood is always increased in a greater or less degree by whatever reduces the velocity of the circulation below that of the healthy state. The blood that first flows from a vein in phlebotomy is not only darker but thicker than that which escapes some time after, on account of its having been brought to a state of rest by the constricting force of the bandage; and as the buffy coat is generally increased under similar circumstances, it would appear that the fibrine had already assumed a disposition to coagulation; for cessation in the motion of the blood, even when very limited in duration, is always accompanied by a tendency to separation in its constituent parts and to coagulation of the fibrine. Hence it follows that ligature, tumours, and other mechanical obstacles situated in various parts of the body, and certain adynamic states, as local and general debility, which retard or arrest the motion of the blood, occasion, in the manner just stated, inspissation and coagulation of this fluid,—effects which often lead to other diseased states that sometimes terminate in death.

It may not be out of place to remark here, inasmuch as it is not our intention to discuss afterwards the changes which take place in the fluids of nutrition and secretion in the different organs of the body, that the study of this physical property, whether existing as a primary or secondary diseased state, seems to us to be one of considerable interest, and, as well as many other still more important changes of these fluids, deserves to be carefully prosecuted, and promises to those whose knowledge of animal chemistry enables them to do so, results of the highest importance. There was, indeed, a time in the history of humoral pathology when some of the physical qualities, and in particular the consistence of the blood and other fluids of the body, attracted almost exclusively the attention of the physician. But, whilst an acquaintance with the laws of fluids in motion enabled him to explain some of the changes which he observed to take place in the circulation of the blood, it was at the same time the great source of the many errors which were introduced into the humoral pathology at the period to which we allude. Nevertheless, not a few of the morbid states of consistence of the circulating and secreted fluids were known to the humoral pathologist, and suggested to him the use of various remedies for their cure.

The doctrines of solidism, as exclusive as those of its now too much neglected predecessor, led away the mind of the physician from the study of the diseased states of the fluids, or induced him to ascribe the origin of those which he occasionally recognized to some previously existing disease of the solids, of which they were supposed to be merely effects, and to be removed by the cure of the primary disease. Such opinions contain much that is untrue as regards the origin of diseased fluids, and even when effects of disease of the solids, it by no means follows as a consequence that the cure of the one will necessarily be followed by the cure of the other. Facts are not wanting to prove the contrary, and to shew the necessity of directing the operation of remedies in such a manner as to effect a salutary change in the pathological conditions of the fluids. But as regards the subject of our immediate consideration—the increased consistence of the fluids of nutrition and secretion—we find not unfrequently examples of this change in the blood of certain individuals labouring under plethora from various causes, and also in many cases of great local congestion, as we have already observed.

Inspissation of the bile is a common occurrence, particularly in the gall-bladder; and here, as in the bloodvessels, the transit of the respective fluids must be more or less impeded by such a change. The formation of gall-stones appears in some instances to depend chiefly on this condition of the bile, which, being thus prevented from passing along the ductus communis choledochus, undergoes the chemical changes necessary for the formation of these accidental products.

Alarming and even fatal consequences arise from inspissation of the mucous secretion of the bronchi, larynx, and even posterior fauces, particularly in individuals debilitated by disease. In such cases the mucous secretion may be perfectly healthy, but having its fluid portion absorbed, it becomes thick and viscid, adheres to the mucous membrane, and accumulates to such a degree as to obstruct the passage of the air, and thus sometimes produces fatal asphyxia. We have ourselves seen the life of more than one individual saved by the removal of this viscid secretion from the posterior fauces and larynx, by mechanical means and change of position. The copious use of cold water given with a view to diminish the plastic property of the blood, is said to have prevented the deposition and formation of the false membrane in croup, or to facilitate greatly its subsequent removal. Are the beneficial effects obtained from the use of mercury in this disease to be attributed to a similar mode of operation?

From these general observations on the diseased states on which induration depends, we may now refer this increase of consistence of the fluids and solids of the body to the following heads:—

1. To a superabundant molecular deposit of solid nutritive matter of the same kind as

that which enters into the healthy composition of a tissue—hypertrophy.

2. To an increase in the quantity of the fluids of nutrition and secretion—various forms of congestion, retention, &c.

3. To a diminution in the quantity of the fluids of nutrition—diminution of bulk from compression.

4. To the presence of solid, fluid, and gaseous, accidental and new products—scirrhus, cancer, &c., hemorrhage, dropsy, œdema, tympanitis, &c.

5. To changes which take place in the qualities or elementary composition of the fluids of nutrition and secretion—thickness, inspissation, coagulation.

It is hardly necessary to observe that several of these diseased states may exist at the same time, and by their combination give rise to compound forms of induration of one or several tissues of the same organ. The characters of each kind are, in this manner, much obscured, and can only be determined by a careful examination of the part, so as to discover the particular diseased state on which each kind depends.

Independently of this source of obscurity, the characters of induration are frequently rendered still more obscure from the changes of bulk, form, and colour with which it is accompanied. The principal changes of bulk which accompany induration are already known to the reader. It is only necessary to remind him that induration may exist without any change in the dimensions of an organ, and that an increase is infinitely more frequently observed than a diminution of bulk.

The changes of form with which induration may be connected are extremely numerous; but as they are of no great importance in the present inquiry, we shall only observe that induration is not necessarily accompanied by any modification of this state.

Various kinds of colour are, perhaps, still more frequently found to accompany the induration of tissues, and modify the appearance which they present in a much more remarkable manner than changes of form or bulk. In the second, third, and fourth kinds of induration which we have enumerated, the sources of the greater number of the changes of colour which accompany these states are obvious. But there are others which are derived from the colouring matter of the blood deposited in tissues, or afterwards modified by the operation of external agents. Hence, the colour of an indurated tissue may be quite healthy, diminished, or increased in intensity, or it may be entirely different in kind; examples of which are met with in hypertrophy, atrophy, congestion, hemorrhage, jaundice, and melanosis.

Changes in the weight, humidity, transparency, and sonorousness of organs, are not only complications, but frequently the immediate effects of induration. Those of weight, humidity, and sonorousness, are all strikingly exemplified in pneumonia terminating in hepatisation; and those of transparency are not rare in membranous tissues.

Having pointed out these sources of complication, we should now proceed to describe the distinctive characters of each kind of induration; but having already entered sufficiently into this part of our subject, which we regard as embracing only the generalities of a morbid state, the physical, anatomical, and chemical characters of which belong to or are derived from other diseases, we have to refer the reader to these diseases, which we have named, for further information on this head. There are, however, certain modifications of function produced solely by the state of induration, and which may be regarded as constituting the physiological characters of this state. These are, modifications of sensation and motion. Thus pain, sometimes of the most acute kind, is produced by the hard unyielding nature of certain tumours compressing or constricting the nerves of sensation distributed to, or which pass in the vicinity of, the diseased organ. Similar effects on the nerves of motion give rise to paralysis. Motion of the solids is, besides, mechanically impeded by induration, which prevents the change of situation and bulk which ought to follow muscular contraction or that of elasticity; and the motion of the blood, bile, urine, and other fluids, may be greatly impeded, or even entirely arrested by the hard unyielding nature of accidental products. Having already pointed out the greater number of these facts which are of any degree of importance, we shall conclude the general part of our subject with a few remarks on the symptoms, causes, and treatment of induration, considered as a morbid affection in the living body.

Symptoms.—The symptoms of induration, considered in a general point of view, are not to be separated from those of the diseases on which it depends; and although the modifications of sensation and motion which we have just noticed are the immediate consequences of this physical change, they do not furnish us with any positive sign of its existence, unless it be at the same time felt or otherwise perceived. Induration, therefore, is not to be detected during life, except in cases in which it is perceived by the touch, or the *mediate sense* of auscultation and percussion,—means which, together with the modifications of sensation and motion mentioned, and those of bulk, form, and colour, to which we have also alluded, will enable us, when properly employed and appreciated, to detect in certain organs the kind, situation, degree, and extent of this morbid state.

Causes.—The causes of induration are also, properly speaking, those of the diseased states on which it depends, and, therefore, anything we might say on this head would be foreign to the present enquiry. Much, however, has been said on the causes of induration, when employed as synonymous with the term scirrhus; but as we regard this state as something more than induration, or induration and hypertrophy united, we think it more consistent with the order which we have hitherto followed, to leave the etiology of scirrhus to be investigated in its proper place.

Treatment.—The principal part of the treatment of induration to which we have to direct the attention of the reader in this place, is that suggested by the modifications induced in the functions of sensation and motion as immediate effects of this physical condition.

When pain arises from induration, and the consequences which frequently follow this change, as weight and tension, it is seldom removed or even much mitigated when seated in internal organs, unless the exciting cause be a fluid. In this case the removal of blood is found to be sometimes followed by great diminution or even the entire cessation of the uneasiness, anxiety, or suffering, which its presence had occasioned; as in great congestion, for example, of the brain and lungs. The good effects of venesection in most cases of plethora are also in part to be attributed to the removal of a quantity of the same incompressible fluid, whereby the organs of circulation, respiration, and innervation are allowed more free and extensive action. The pain which always accompanies the vascular tension of an inflamed part, and more particularly that occasioned by the effusion of serum and pus in the cellular tissue, and beneath unyielding fibrous coverings, is still more remarkably relieved by the destruction of the constricting causes and the evacuation of the incompressible fluids. The relief which patients experience on the removal of the fluids collected in the cavity of the pleura and abdomen in acute inflammation of their respective serous coverings, in some forms of ascites and oedema, in retention of the milk, urine, &c. is to be attributed in no small degree to the judicious application of the same principle.

When pain is occasioned by the pressure of a hard tumour, it may be mitigated or removed by the following means—change of position, warm fomentations, anodynes, extirpation, and other mechanical means. Change of position seldom accomplishes much in the way of removing pain, and has only been found to be occasionally suggested by patients themselves who have accidentally discovered that their sufferings were relieved when in certain positions; as in some cases of pendulous tumours contained in cavities.

Warm emollient applications, from the relaxing effect which they produce on the parts to which they are applied, are often of the greatest benefit. Independent of the benefit which for a time may be derived from the general administration of anodynes, more decided and more permanent advantage has of late been obtained from their local application, in the manner recommended by some French physicians, and called by them *la méthode endermique*.^{*} This method, so far as we know, has not been employed to remove pain produced by the pressure of hard accidental products or tumours; but from its successful application in several cases of acute and

^{*} *Essai sur la Méthode Endermique*, par Ant. Lambert, Paris.—*Trousseau*, Journ. Univer. et Hebdom. de Méd. et de Chir. Pratique, tom. iv. p. 82.

chronic neuralgia in external parts of the body, we feel strongly disposed to believe that the continued and sometimes excruciating pain which accompanies certain subcutaneous and even deeper-seated tumours of the nerves, would be greatly relieved or entirely removed by the application of the salts of morphia or belladonna (the remedies hitherto employed) to the denuded skin in the tract of the affected nerve. The cure of these cases and others of a similar kind belongs, however, to the province of surgery, and consequently we can only name the third mode, viz. extirpation, excision, and other mechanical means employed in that department of medicine.

With regard to the means to be employed with a view to facilitate the motion of solids and fluids, impeded by an abnormal increase of consistence, we have little to add to what we have already suggested on this head. The physician when compared with the surgeon is wonderfully limited in the means which he has to employ in many of these cases. Those remedies alone which exercise a special influence on the great function of nutrition in general, or on those of hematosis, circulation, absorption, and secretion in particular, seem sometimes to afford a well-grounded hope that many of the diseased conditions which give rise to induration are not altogether beyond the salutary influence of medicine.

SPECIAL PATHOLOGY OF INDURATION.

Having entered rather fully into the general pathology of induration, we do not think it necessary to discuss the special pathology of this disease, unless in the two following cases—induration of the cerebral substance, and induration of the cellular tissue.

I. Induration of the cerebral substance.—Perhaps no term has been more vaguely employed by physicians to designate a particular diseased state of the brain than that of induration. There are, in fact, few accidental products which, at one period or other of their development, and formed in the substance or on the surface of the brain, have not been described as induration of this organ. Much of this ambiguity has, however, been removed by a more accurate knowledge of the anatomical characters of these diseases; and however obscure or uncertain may be the origin, nature, symptoms and treatment of many of them, their being thus brought before us under a distinct and tangible form has already been productive of much good. It is, perhaps, owing to this circumstance alone that so much progress has of late years been made in the pathology of the brain.

The substance of the brain is, as we have already said, subject to an increase of consistence independent of the presence of any foreign product deposited within or upon it. It is only under such circumstances that we admit the existence of induration as a disease. Hence, it is only in certain forms of hypertrophy and atrophy that we find a simple increase of the consistence of this organ. It is, however, by no means easy in every case to determine that an increase of consistence depends alone

on a modification of one or other of these conditions of nutrition; for colourless effusions, containing a greater or less quantity of albumen and fibrine, may take place in the fibrous texture of the brain, and produce various degrees of consolidation of the cerebral substance. But when such effusions are not to be detected; when there is no other morbid product present; when the brain or a portion of it is harder than we know it should be at the period at which it is submitted to our examination, we are then to consider it to be in a state of simple induration, whether its colour be altered or not. The degree and extent of such a condition of the cerebral substance may present very considerable variation. Sometimes the increase of consistence is so slight that we only admit its existence as probable; at other times it is so great as to be perceived even before it is touched, on account of the softer surrounding substance falling down when divided, and leaving the indurated portion more elevated. If, in the first case, the augmentation of consistence be circumscribed instead of being general, we have then in almost every case the means of determining how far it is a pathological state, by comparing the part supposed to be diseased with the corresponding healthy part,—a mode of examination which ought always to be had recourse to under similar circumstances in every organ of the body whenever it can be employed. We of course suppose that a previous knowledge has been acquired of the several degrees of the healthy consistence of the brain in general, and of its parts in particular.

The several degrees of morbid increase of consistence of the cerebral substance may be represented to the mind of the reader by the changes of consistence which the brain itself undergoes after it has been submitted to the action of alcohol, acids, or boiling oil, for a given length of time. It then cuts like the white of a hard-boiled egg, the udder of the cow when boiled, or firm smooth cheese, such as that of Gruyère. It has been represented to be sometimes as hard as fibrous or cartilaginous tissues; but such degrees of induration of the brain do not, we believe, exist as simple states, and depend on the presence of accidental tissues.

The greater the degree of induration, the greater the change of colour the affected part undergoes: this consists in a diminution or entire want of the natural colour of that part. Hence, the natural colour of the medullary substance being pale, a diminution of colour is principally observed in induration of the brown or cortical substance, which may become so pale as not to be distinguished from the medullary with which it is in contact.

The first as well as the succeeding degrees of induration may present this state of pallor, but it may likewise be redder than natural. In the former the substance of the brain, when cut, is sometimes moistened with serosity, at other times drier than natural; in the latter it presents a greater number than usual of red points or streaks of blood. A thin slice of

the indurated portion may be held out between the thumb and fore-finger, and, when pressed, sometimes snaps through like a bit of boiled albumen. It is only when this diseased state is circumscribed that it has been observed to be great in degree; and when it occupies the whole brain, it generally amounts to little more than what may be called a state of firmness.

An increase of bulk in induration of the cerebral substance is not easily ascertained unless the affected part be in the convolutions, in some of the circumscribed and distinct portions of it, or occupies the whole brain. A diminution of bulk accompanying the same state presents the same difficulties. Both, however, have been observed; but the former much more frequently than the latter.

The brain is far more frequently the seat of induration than the cerebellum; the cortical substance perhaps more so than the medullary; the peripheric portion of the latter than the central; the basis than the surface of the hemispheres.

The medulla spinalis, in which this change has also been observed in a circumscribed or general form, is much less frequently affected than the brain, and has seldom been seen to acquire the same degree of morbid consistence, except at its upper portion, and more particularly the medulla oblongata.

Symptoms of induration of the brain.—Of the various authors who have observed and described induration of the brain and spinal marrow, some of them have regarded it, when general, as giving rise to ataxic or typhoid fever, and some forms of mental derangement, being in the former an acute, in the latter a chronic state of disease. Others have endeavoured to shew that tetanus, epilepsy, and other nervous and convulsive disorders, may also sometimes originate in the circumscribed form of the same pathological state. Whilst we add our testimony to the truth of the anatomical part of the facts on which these opinions have been founded, we must at the same time say that we feel but little disposed to place much reliance on the diagnostic value of the symptomatic details which these authors have collected on this subject. In the present state of our knowledge we believe that we possess no means of detecting the existence of induration of the brain and spinal marrow during life, the symptoms which have been found to accompany it—such as various modifications of sensation, motion, and intelligence—being common to many very different morbid states of the same parts. The derangements of function which follow as the immediate consequences of induration of the cerebral substance are, indeed, sufficiently obvious to the physician; but, for the reasons just stated, they afford him little or no assistance in determining the nature of the lesion on which they depend.

Causes.—The etiology of this morbid state is by no means so well understood as some pathologists would have us believe. That certain forms of it depend on a previous state of irritation every one must admit; but that

this state of irritation, or any modification of it, is the sole cause of induration, is by no means in accordance with the results of observation. In that firmness of the brain in general, observed in some forms of fever accompanied with more than ordinary excitement, and in some cases of acute hydrocephalus, in some kinds of mania accompanied or not with paralysis, irritation of the brain or its membranes may be regarded as at least the probable cause. Circumscribed induration of the cerebral substance may also originate in the same cause, inasmuch as we find it present and in juxta-position with other diseased states, such as ulceration and abscess, having a similar origin. But for reasons equally cogent, we are led to reject the evidence on which it has been attempted to establish the general application of this principle to the etiology of this disease. When, as we have stated in the introductory part of this article, we find that portions of organs, and even whole organs, acquire a great increase of consistence without presenting any, even the slightest, modification of function such as is observed to accompany irritation; that the same organ (the brain too) is soft at one period of life and firm at another; that an organ that is soft in one animal is hard in another; we cannot resist the conclusion that increase of consistence,—that is, induration,—when occurring out of the usual order of place and time, may nevertheless be something else than a consequence of any morbid state with which we are yet acquainted, however much we may pretend to be familiar with its ways of working. It would seem to us to be much more consistent with a sound philosophy to attribute the production at least of some of the forms of induration of organs to the influence of other and still more general laws than those of irritation, viz. those of organization; and, moreover, that instead of occupying the rank of a cause, irritation in this as well as in numerous other instances, follows as an effect, and thence becomes a valuable evidence of the existence of the former.

Treatment.—As the causes of induration are obscure, and more particularly as we are unable to recognise the existence of this state during life, we have of course no indications or modes of cure to propose. We except, however, from this barren and unsatisfactory result that form of induration which we have stated may arise from an augmentation in the quantity of blood usually admitted into an organ. Such is the state of the brain in congestion, the treatment of which is given in another place. It may not be unimportant to remark that the principal phenomena of congestion, loss of sensation and motion, seem to be the immediate effect of the state of induration induced in the cerebral substance by the accumulated blood: the degree of density alone, which is thereby induced, being sufficient to unfit the organ for the accomplishment of its functions, independent of the other changes which we well know follow as a consequence of such congestion.

II. *Induration of the cellular tissue.*—*Syn.*

Induratio telæ cellulosa; sclerema; squirrhosarque; œdème concrète; œdème du tissu cellulaire des nouveaux nés; zellgewebsverhärtung; skin-bound disease.

The cellular tissue affords so many facilities for the formation and development of disease, that it has been regarded by several pathologists as the primary seat of almost all morbid products. Various circumstances, the exposition of which does not come within the scope of this article, concur to give rise to such a belief, but which is as little founded in fact as every other exclusive theory regarding the common origin of diseases. The pathological state which we have to examine furnishes a striking example of the fallacy of such generalising principles, induration of the cellular tissue being, in point of fact, one of its most equivocal characters.

Induration of the cellular tissue constitutes a case of complicated induration, depending exclusively, as regards the local affection, on an accumulation of serosity or sero-albuminous fluid in the cellular tissue. It is therefore only in accordance with custom that we have introduced this state under the appellation of induration of the cellular tissue. We shall, however, employ the term *œdema* (instead of induration) of the cellular tissue, as it fully and accurately expresses the condition on which the induration depends, to which we may add *of new-born children*, to distinguish it from that which occurs at an after period of life. Although this affection is generally observed in children a few hours after birth, it may occur several days later; and there are examples of children having been affected with it when born.

The subjects of this disease are for the most part feeble; sometimes imperfectly developed, and generally born before the full period. They do not seek the breast, but refuse to suck; they are agitated almost continually, and have a peculiar cry. The skin is dry, cold, as if stretched; generally of the natural red colour, but sometimes purple or livid. The soft parts feel firm, or even hard; when pressed they become pitted, and of a dull yellow colour; but the primitive form and colour soon return, unless the œdema be extreme. These appearances are generally observed to begin in the inferior extremities, passing from the feet upwards, and sometimes proceed with great rapidity, attacking the hands and arms; the inferior part of the abdomen, back, and face. Sometimes it appears to affect almost all these parts simultaneously, and nearly to the same degree. More rarely it is confined to the feet and hands. The bulk of the affected parts is increased, particularly that of the inferior extremities, but by no means in proportion to the degree of induration which they communicate to the hand when pressed. The diminution of temperature of the affected parts follows in a descending ratio the progress of the œdema, and in some cases has been observed to precede it. The production of heat is rapidly diminished over the whole body; the inferior extremities become quite hard and

stiff; the superior extremities and trunk less frequently to the same degree. In extreme cases the application of heat to the body only acts upon it as on dead matter, its temperature being suddenly raised or cooled as the warming medium is applied to or removed from it.

The other signs of functional derangement which accompany this affection increase in severity with the same rapidity. The respiration, at first imperfect, becomes difficult and laborious, and the pulse so feeble as sometimes not to be felt. In this state death supervenes from asphyxia, generally within the fourth day, sometimes on the first, and more rarely at the end of one, two, or even three weeks.

These are the most prominent and remarkable symptoms; those which may be regarded as proper to the disease. The symptoms of jaundice, although frequently present, are, however, perfectly distinct from those of this form of œdema. The same may be said of those of cerebral, gastric, intestinal, and acute pulmonary affections, which have been regarded by some as giving rise to the affection.

The characters of this disease are so well marked that it cannot be confounded, unless when circumscribed, with any other disease by the most careless observer; and even in this form it is only necessary to note the diminution of temperature which accompanies the œdematous swelling, to distinguish it from any inflammatory affection of the skin which gives rise to a similar state of the cellular tissue, and in which the temperature of the affected part is always morbidly increased.

It is rare that the physician has the satisfaction of being able to pronounce a favourable prognosis in this affection after it has arrived at a certain stage. It is only when the œdema is limited in extent and not great in degree; when the circulation and respiration are not much affected; when the temperature has not sunk much below the natural standard, and when the strength of the infant can be supported by its taking the breast, that a favourable termination may be reasonably expected. In such cases, as well as in those of a severer kind which recover, the signs of a favourable issue are to be drawn from the amelioration which takes place in the state of the respiratory function, which becomes less embarrassed; the increasing strength of the pulse; the gradual elevation of the temperature of the skin; the diminution of the swelling, and particularly of the induration; the disappearance of the deep red or livid colour which it may have presented, and the supervention of a gentle moisture over its hitherto dry surface—the child becomes quiet, sleeps, and manifests a desire for food.

Before proceeding to examine into the causes of œdema of the cellular tissue of new-born children, we shall, in the first place, endeavour to give a correct statement of the facts which the morbid anatomy of this disease has enabled us to collect.

The external aspect of the body is but little changed after death. The affected parts still preserve the same colour; the face and upper part of the trunk are even more swollen, and

the induration in general is rather increased than otherwise; the softer parts, such as the face, evidently so.

When a section of an œdematous extremity, the leg for example, is made so as to expose fully the subjacent cellular tissue, instead of finding this tissue compact and indurated, we find on the contrary its cellular aspect much increased, from the cells being filled with a serous or sero-albuminous fluid, which is either quite limpid, of a citrine colour, or tinged with blood. The quantity of this fluid is in proportion to the degree of swelling and induration which accompanies it. If small in quantity, the cellular tissue requires to be pressed before its presence can be recognised; but when abundant, it distends the cells of the subcutaneous cellular tissue, and a part of it oozes or flows out from the compression which the divided skin exercises upon it, or by its own specific gravity. When the whole of this fluid is forced out by pressure from the subcutaneous cellular tissue, it then feels soft and extensible; and the skin, which was before stretched and fixed, becomes lax, and can be moved over it as in the healthy state. When examined narrowly, it is found to present no thickening, opacity, or change of consistence. Its colour may be natural, or reddened by a slight degree of vascularity. The intermuscular cellular tissue may present the same appearances, but in a much less degree.

When the serous effusion occupies the adipose as well as the cellular tissue, the feeling of hardness is increased. The granules of fat, so conspicuous and firm in the child, are in this way compressed between two forces. They appear whiter than usual, resemble the fat of meat, and are hard, as if frozen. This state of the adipose tissue does not necessarily accompany œdema of the cellular tissue, as it occurs frequently without it.

From these facts, the truth of which we have had ample opportunities of verifying in a large hospital set apart for the reception of new-born children—the *Enfants Trouvés* at Paris, it must appear obvious that the state of induration observed in these children is a purely mechanical effect, depending on the accumulation of a fluid in the subcutaneous cellular tissue. The term induration never could have been employed to designate such a morbid state, had those who first observed and described it submitted the affected parts to careful anatomical investigation. Denman, Underwood, and others since their time, have stated that the cellular tissue, in the cases which they observed, was not only hard but *dry*. As we have never met with one example of such a nature among the great many cases which we have examined, and as we know that the disease which they described is the same as that of which we are now treating, we feel disposed to doubt the reality of such cases. It would serve no good purpose to multiply facts to prove that those pathologists have been also deceived who have described the cellular tissue in this disease as thickened and hardened; particularly Allard, who considered it in this

respect as analogous to the elephantiasis Arabum, or what is commonly called Barbadoes leg. (See ELEPHANTIASIS.)

The presence of a greater or less quantity of serosity or sero-albuminous fluid in the subcutaneous cellular tissue constitutes the essential anatomical character of the disease we are describing; and in this respect it is to be regarded as œdema, differing perhaps little even in its nature from that which is much more commonly observed in adults, as a consequence of disease of the organs of circulation and respiration, and in whom it also presents to the touch the sensation of various degrees of induration.

Not satisfied with this simple explanation of induration of the cellular tissue of new-born children, some pathologists would have the effused fluid possess the property of becoming concrete, and to this circumstance they attribute the degree of hardness which the affected part communicates when pressed. For this reason also, they regard it as different in its nature from the œdema of adults, and have on that account, and to distinguish it from the latter, called it *concrete œdema*. The results of some experiments made by Chevreul on the effused fluid taken by Breschet from the cellular tissue of children affected with œdema and jaundice at the same time, (a very frequent complication,) appeared to confirm the opinion that the induration depended on the coagulable nature of this fluid. Subsequent experiment, however, has shewn that the inference drawn from the fact of the coagulable property of the effused fluid was by no means correct; for not only is this fluid not found in a concrete state in the cellular tissue of new-born children affected with œdema, but the property which it possesses of coagulating spontaneously when placed in a state of rest, and exposed to the influence of the ordinary temperature of the air, exists also in the fluid found in the cellular tissue of adults affected with ordinary œdema. In all cases, in fact, of œdema produced by an obstacle to the return of the venous blood, does the effused fluid possess this property; and so far as our experience enables us to judge, the more sudden the production of the œdema, the greater the spontaneous coagulability of the effused fluid. Hence the reason why in the œdema of new-born children, in whom the effusion generally takes place rapidly, this coagulable property is more marked than in the chronic œdema of adults. Notwithstanding these facts, we must repeat that the state of induration is neither caused nor increased by this circumstance, for we have never found the fluid coagulated in œdema of the cellular tissue after death. That it is not coagulated during life we know, from the fact that it flows out when the skin is punctured.

Besides the state of the cellular tissue which we have described, various morbid appearances are observed in different parts of the bodies of those who die of infantile œdema. Some of these are always present, and are therefore to be regarded as essential to the production of

the disease; others are only occasionally met with, and on that account must be viewed in the light of coincidences.

The most remarkable among the constant lesions is a state of general venous congestion. The heart and great bloodvessels are filled or distended with blood; the lungs and liver, and indeed all the soft parts, are in a high state of congestion, particularly the former, which, when cut, discharge a great quantity of dark venous blood. There exists no mechanical obstacle in the heart, great bloodvessels, or lungs, to which this accumulation of blood can be attributed; and on that account it resembles plethora more than any other affection.

We need hardly observe that it is to this state of general congestion that the effusion of serosity in the cellular tissue is to be attributed, and that the same state of congestion, and the œdema which follows it in the lungs, are the causes of the difficulty of breathing which is present in this disease. The languid state of the circulation, and the stagnation of the blood in the capillary system in general, appear to us sufficient to account for the remarkable diminution of temperature which takes place in infantile œdema.

With this state of congestion there is, also, a greater or less degree of œdema of the cellular tissue of the viscera of the thorax and abdomen, and effusion of the same fluid into the serous cavities. The submucous cellular tissue in general is more or less œdematous; and it is this state of that of the glottis which occasions the cry peculiar to children affected with this kind of œdema.

These are the most remarkable of the constant lesions in infantile œdema. Those which occur accidentally, but which have been regarded by some pathologists as the causes of this kind of œdema, are numerous. The principal of them are acute affections of the lungs and liver, of the stomach and intestines, or of these and the subcutaneous cellular tissue at the same time; the non-occlusion of the foramen ovale; and a diminution in length of the intestinal tube.

Without denying that most of these morbid states, and some of them much more than others, contribute, when present, to increase the effusion into the cellular tissue, we are more disposed to believe that they are much more efficacious in retarding or rendering its cure impossible; and we are persuaded that they have no direct effect in producing it, since we have found it to exist in an extreme degree, when there was no other appreciable morbid condition to be detected but the general state of congestion which we have described.

After these remarks we trust it will not be considered an omission, if we overlook most of the theories, or rather hypotheses, which have been entertained regarding the etiology of œdema of the cellular tissue of new-born children.

Andry and Auvity, the first who gave a good description of this disease, attributed its production to the action of cold; but although it occurs more frequently in winter than at any other time of the year, it is often observed in

summer and under circumstances the most favourable as to external temperature.

The opinion of Breschet, that the effusion of serosity in the cellular tissue depends on the permanent opening of the foramen ovale, was soon shown to be unfounded. Indeed it is difficult to conceive how this intelligent pathologist could have offered such an opinion as the result of his observation. "In seventy-seven children," says Billard,* "affected with œdema of the cellular tissue, there was in forty of them complete occlusion of the foramen ovale, and in twenty-eight of these even the ductus arteriosus was considerably contracted, and did not allow the passage of the blood through it. The explanation of Mons. Breschet falls, therefore, before the evidence of facts. If the foramen ovale is still found frequently open in *hard children*, it is because induration of the cellular tissue affecting particularly very young children, the changes which take place in the heart and ductus arteriosus of the new-born child, after the establishment of the independent circulation, have not had time to be completed when the œdema appears. I think, therefore, that there is no relation between the two phenomena in question."

The last opinion which we shall notice is that of Mons. Denis, who has endeavoured to shew that an inflammatory condition of the cellular tissue which becomes affected with œdema, and of the mucous membrane of the stomach and intestines at the same time, are the causes of this disease. To characterize this complication, and no doubt anxious to do honour to the *Doctrines Physiologiques*, Mons. Denis has conferred upon it the appellation of *phlegmasie entéro-cellulaire*. Inflammatory affections of the gastro-intestinal mucous membrane are extremely common in infants, and must consequently be met with in those affected with œdema of the cellular tissue; and when we find œdema without them, and vice versa, we are not permitted to regard their simultaneous existence otherwise than as a coincidence. That the œdema of the cellular tissue is the consequence of inflammation, no pathologist who has examined it, and whose judgment is not biassed by preconceived notions, will believe. Were such the fact, we should find sometimes, if not always, some of the products or effects of inflammation of the cellular tissue, such as coagulable lymph or pus, or softening; which we ourselves (or, we believe, any body else, not excepting even Mons. Denis,) never once have met with.

Mons. Baron, who for a number of years has been physician to the *Enfans Trouvés*, regards the œdema of new-born children as analogous in every respect to that of adults.

An accurate observer and distinguished pathologist, Mons. Billard, who has had ample opportunity of studying this disease, considers its predisposing causes to be, 1st, a natural state of debility of the new-born infant; 2d, a

* *Traité des Maladies des Enfants Nouveaux-Nés*, &c. Paris, 1828.

state of general congenital plethora; 3d, a superabundance of venous blood in the tissues; 4th, a state of dryness of the skin before the exfoliation of the epidermis: and the direct causes, 1st, an obstacle to the course of the blood, resulting from the abundance of this fluid in the circulating system; 2d, its regurgitation in the cellular tissue, to which it furnishes an inordinate supply of the materials of secretion; and lastly, the action on the skin of external agents, which, without condensing, as has been said, the serous fluids, are capable of suspending the cutaneous transpiration, and thereby favour the accumulation of the serosity in the cellular tissue.

Treatment.—Reasoning on the evidence which we have endeavoured to lay before the reader on the nature and causes of infantile oedema, the curative indications which it suggests are but few in number. The state of general venous congestion that prevails; the diminution of temperature which accompanies this state; the dry atonic condition of the skin, and the state of debility of the little patient, constitute the chief points in the pathology of the disease to which the attention of the physician is to be directed. With a view to diminish the quantity of the blood, and thereby favour its circulation, leeches may be applied to the chest or oedematous parts; a practice which, although we have not seen it fairly tried, is said to have been remarkably successful in the hands of Palletta.

A more safe, and perhaps equally successful method of treatment employed to accomplish the same end, consists in the use of repeated friction with warm flannel, the body in the intervals being well covered with the same material, which is not to be allowed to become cool. The vapour-bath has been recommended; but it has not been found to answer the expectations of some physicians who had ample opportunities of giving it a fair trial. Mons. Baron has found friction and the application of warm flannel to the skin much more beneficial. The difficulty of breathing is sometimes greatly increased while the child is in the bath, and congestion and even sanguineous effusion have been known to take place in the lungs and brain soon after its administration.

If, under the judicious use of the means we have recommended, the pulse improves and becomes steadily more strong, the temperature soon rises, and the physician has the satisfaction to perceive that a gentle moisture breaks out over the surface of the skin. The oedema soon after begins to diminish, and with it the induration which it had occasioned; the motions of the child become more free, and the cry natural; the desire for food returns, and convalescence is complete, sometimes in a few days. Although we are not acquainted with any method of treatment so successful as that which we have recommended, it requires in many cases, either on account of their severity, the debility of the child, or the co-existence of other affections, much discrimination on the part of the physician, and a degree of care and patience not often to be found in

those in whose hands it may be said the lives of these little sufferers are placed, to regulate its application, and obtain from it its beneficial effects.

Acute affections of the lungs, stomach, and intestines, are, as we have said, extremely frequent at the same period, and when severe, destroy, perhaps, a greater number of children affected with them than the disease which we have described, and for which no mode of treatment can then be said to offer any reasonable hope of accomplishing a cure.

(R. Carswell.)

INFANTICIDE.—Before the end of the seventeenth century, medical men were not consulted in cases of infanticide. In the criminal code* of the Emperor Charles V. it was merely directed that the breasts and parts of generation should be inspected by an experienced and sensible woman, and the delivery being, as it was supposed, ascertained, the proof of the death of the child at birth was imposed on the mother. We are told also by Bohn† that a mother suspected of infanticide which could not be proved, was put to the rack to extort confession of her imputed guilt. In this country the statute of James I. was conceived in a similar spirit, for it concluded the mother to be guilty of the murder of her child, who could not prove, by at least one witness, that the child was actually born dead; a condition under certain circumstances obviously impossible, and thus rendering the statute unjust in its operation by confounding the unfortunate with the guilty. This act continued in force for nearly a century, but at length it became customary to require more direct proof of homicide; and by an act passed in the 43d of Geo. III. it was provided that trials for infanticide should be regulated by the same rules of evidence and presumption as were usual in other trials for murder; and thus the subject was brought more distinctly within the pale of medical enquiry.

Infanticide has been divided into feticide, or the destruction of the fœtus whilst yet in the womb, commonly called criminal abortion; and infanticide strictly so called, or the destruction of the life of the child either newly born or in the course of parturition. The present article will treat of the latter division only; and the evidence respecting it naturally divides itself, 1st, into that which has reference to the child, and 2dly, into that which relates to the mother. The investigation of the following questions will comprise the most material points of medical evidence:

1. Was the child born living or dead?
2. What was the cause of its death?
3. Has the suspected mother been recently delivered?
4. Do the phenomena presented by the supposed mother and child confirm the suspected relationship?

* Beobachtungen und Abhandlungen von österreichischen Aertzen, 3er. Band. Wien. 1823.

† Dissert. binæ de partu enecato, p. 336.

Writers on infanticide, in proceeding to discuss the first question in the enquiry, have generally deemed it necessary to prefix a statement of the development of the fœtus at the different periods of utero-gestation, a knowledge of which is requisite in proving the *viability* of the child, that is, its capability of supporting extra-uterine or independent existence. Some difference of opinion has existed concerning the precise period from which the viability of the child should be dated; but it is generally agreed on among medico-legal writers, that no well authenticated examples are recorded of children living which had been born before six months of utero-gestation.* An exception to this opinion may be thought to have occurred in a case recorded by Dr. Rodman,† who describes his patient as having been delivered at the end of the 19th week of pregnancy. The feebleness of the child would appear to justify the correctness of Dr. Rodman's opinion, for when three weeks old, it measured but eleven inches in length, and weighed two pounds and a half avoirdupoise, the clothes forming eleven ounces of this weight. But a case has subsequently been published by Mr. Baker, which renders it probable that Dr. Rodman was mistaken, for the child described by Mr. Baker,‡ although born undoubtedly at the full period of utero-gestation, corresponded pretty closely with the one alluded to by Dr. Rodman. The absence of all allusion to the external characters of the child in the latter instance prevents any reliance being placed on it. If the membrana pupilaris had existed, it may be reasonably presumed that it would not have eluded Dr. Rodman's observation, nor escaped remark.

A description of the leading phenomena which the organization of the fœtus presents from the fourth to the ninth month will include everything on the subject which can be interesting in relation to infanticide; and these phenomena relate to its length and weight, the proportional length of its parts, the state of the skin and its appendages; of the pupil of the eye; of the internal viscera, particularly of the abdomen; of the organs of generation; of the brain; and lastly, the progress of ossification. The weight and absolute length of the body furnish but uncertain data, since they vary much in different fœtuses at the same age. But Chaussier§ has pointed out an excellent criterion, founded on a very extensive examination of subjects, in the comparative length of its several parts at different periods. If in a well-proportioned adult a line be drawn from the top of the head to the heel, its centre corresponds with the upper edge of the pubis. But in the fœtus this central point is situated much higher; for in a mature child it corresponds with the umbilicus or a little above it;

at the end of the eighth month it is about an inch higher; at the end of the seventh still nearer the sternum; at the end of the sixth it falls just at the end of that bone.

The average weight of the fœtus at four months is from five to seven ounces; at five months, about a pound; at six months, two pounds; at seven months, from three to four pounds; at eight months from four to five pounds; at nine months the average weight in this country is about seven pounds,* the most frequent range being from five to eight pounds. Lecieux and Bernt have remarked that the length of children at the full period is less liable to variation than the weight. The following is a transcript of the table of the former.

Months.	Inches.
4	5 to 6
5	9½
6	12
7	14
8	16
9	18

And he agrees with Baudelocque in stating the extremes in mature children to be from sixteen to twenty-two or twenty-three inches.†

At the *end of the fourth month* the skin is rosy and moderately dense. The pupillary membrane is very visible; the meconium a little coloured, and occupying the commencement of the small intestines. The brain exhibits the interlobular furrow. There is a commencing ossification of the vertebrae of the sacrum. The kidneys are very voluminous, consisting of from fifteen to eighteen lobes, the suprarenal capsules being as large as the kidneys.

At the *end of the fifth month*, the scalp is covered with short silvery thinly scattered hair; the skin is of a deep red colour, but without sebaceous covering; the adipose membrane is but little developed; the nails are scarcely perceptible. There is commencing ossification of the first bone of the sternum, of the pubis and os calcis. The volume of the lungs is small, the heart is large, the ventricles little distinguishable from the auricles; the liver very large and near the navel, consisting of two equal lobes. The gall-bladder contains a little, almost colourless, serous fluid; the spleen is little developed and close to the stomach; the meconium is in small quantity, and only occupies the cæcum and a small portion of the colon. In the male fœtus the testicles are situated beneath the kidneys, near the lumbar vertebrae. In the female the ovaries are small, soft, elongated, very distinguishable from, and in a similar situation to, the testicles in the male. The brain on the surface is smooth, but several deep furrows and convolutions are now visible on the inner aspect of the hemispheres where they are applied to the falx cerebri.

At the *end of the sixth month*, all the external parts are very distinct. The skin is very

† Médecine Légale ou Considérations sur L'Infanticide, p. 11.

fine, of a deep red or even purple colour, particularly in the palms of the hands and soles of the feet, face, lips, ears, and breast. The stomach is filled with mucus; a part of the large intestines with meconium. The colon begins to exhibit its sacculated character. The testicles are still in the abdomen under the peritoneum. The bladder, hard, pyriform, and above the pelvis, has but a small cavity. About this period two points of ossification are formed in the second cervical vertebra; near the seventh month the superior point, which answers to the odontoid process, is larger than the inferior, which relates to the body of the bone. According to Tiedemann, the posterior lobes of the cerebrum now cover the corpora quadrigemina, and almost the whole cerebellum. The three cornua of the ventricles are quite distinct. The choroid plexus is very voluminous. The laminae of the septum lucidum are joined so as to form the fifth ventricle. The corpus callosum extends further backward, but does not yet cover the thalami and third ventricle.

At the end of the seventh month the skin is dense and fibrous, and is covered with the *vernix caseosa cutis*, unequally thick in different parts of the body. The pupillary membrane has disappeared. The hair is longer and of deeper hue; the nails are firmer, but do not extend to the ends of the fingers. The bile is yellowish and bitter. The meconium occupies a considerable part of the large intestines. The valvulae conniventes begin to appear. The testicles and ovaries are nearer the pelvis. The posterior lobes of the cerebrum now cover and extend beyond the cerebellum, and several furrows and convolutions are observable on the surface. The corpus callosum covers the thalami, and consists of transverse fibres passing from one hemisphere to the other. The corpora quadrigemina are divided by a transverse line or furrow rendering them complete and distinct, the two superior, or nates, being somewhat longer than the two inferior, or testes, and their parietes so thick that the iter a tertio ad quartum ventriculum may be considered perfect.

At the eighth month the skin becomes covered with very fine short hairs, the skin itself is denser and whiter, and the nails are firmer and more elongated. The sebaceous covering is more general. Oftentimes the breasts are projecting, and a milky fluid may be expressed from them. In the male the testicles are generally engaged in the abdominal ring. About this period the transverse processes have begun to ossify in the first lumbar vertebra. The structure and configuration of the interior parts of the brain, already completely formed, have only to be augmented in volume, the surface to be farther developed. The two hemispheres of the cerebrum extend backward considerably beyond the cerebellum. The hemispheres on each side are traversed with furrows, into which the folds of the pia mater enter, but these furrows, or the convolutions which they produce, are no where so marked as on the anterior and middle lobes.

At nine months ossification is more complete.

The descending ramus of the os pubis and the ascending ramus of the ischium are consolidated. Ossification has commenced in the first cervical vertebra, and also in the first bone of the coccyx. The body of the fourth lumbar vertebra, which is the most voluminous, is three lines in depth and six in breadth. The lateral portions of the six superior dorsal vertebrae begin to unite so as to form a ring posteriorly to the bodies of these bones. The bones of the cranium, although moveable, are in contact at their margins. Generally the testicles have passed the abdominal ring, or even descended into the scrotum. The nails are thicker and firmer, and are prolonged to the extremities of the fingers. Capuron states that the grey matter is now visible in the brain, but Tiedemann asserts that at no period is it possible to distinguish between the cortical and medullary substance in the fetus.

We shall not be understood to pretend that the preceding details will be found precisely to indicate the age of the fetus. Much variety is found in different children at the same age; but an attention to the criteria now laid down, particularly as they relate to the progress of ossification; to the development of the brain, and relation of the umbilicus to the centre of the body, for which we are indebted to Béclard, Tiedemann, and Chaussier, will enable the enquirer to form a tolerable approximation to the truth.

The advantage arising from the investigation of the anatomy of the fetus is, that it enables the enquirer to decide on the maturity or immaturity of the child, and to set at rest its capability of being born alive. If the child were mature, the greater is the probability of its having been born living; if immature, the likelihood of death from natural causes is considerable. And in either case it is creditable to the investigator, and indeed necessary in drawing up a medico-legal report on a child found dead, to indicate with some precision the age of the subject under examination.

I. At the time when concealment of birth and evidence of the life of the child were allowed to form conclusive proofs of the commission of infanticide, the enquiry, *whether the child was born living or dead*, was of paramount importance; and it is still one of considerable interest to the medical jurist and lawyer. The proof of the child having been born alive forms, in trials for infanticide, presumptive evidence in favour of the charge; whilst evidence of its having been still-born will confine the investigation to the proofs of death from criminal violence during parturition,—a species of child-murder commonly requiring the aid of an accomplice, and hence an infrequent form of infanticide.

The proofs of the survival of the child after delivery must be drawn from the phenomena of *respiration and circulation*, as it is chiefly by the performance of the former, and the changes which take place with respect to the latter, that the commencement and continuance of extra-uterine life are indicated. These phenomena relate principally to the colour of the

lungs, their consistence, specific and absolute weight, and their volume; to the contraction of the ductus arteriosus Botalli, and its diameter in relation to that of the pulmonary artery and its two great branches.

1. *Colour*.—The colour of the foetal lung is dark red, sometimes inclining to the brownish red of the liver, or the blueish red of the thymus; but in those parts of the lung in which respiration has had an influence, it is pale red or scarlet, unless they are gorged with blood, in which case it may be brownish or blueish red. From the experiments of Bernt* it results that artificial respiration in a dead child, if it change the colour at all, causes a pale or grayish red tint. In children who have breathed imperfectly, or only for a short time, the lungs on the anterior surface are of a pale red, on the posterior surface dark red, whilst in different parts of the lungs patches of scarlet red are visible. In children who have breathed perfectly and lived a longer time, the lungs are pale red with numerous patches and stripes of cinnamon or scarlet-red; posteriorly they present a dark red colour, owing to the subsidence of the blood.

2. *Consistence*.—The lungs, in the foetal state compact, become from respiration looser and expanded. They are vesicular on their surface, and air-bubbles or froth may be squeezed out of them. These are circumstances to be determined by the touch and sight, and result from their mechanical distention by the air. Three sources have been enumerated, besides natural breathing, from which air found in the lungs may be derived, namely, artificial inflation, putrefaction, and emphysema. The two latter produce vesicles which are superficial, large, and irregular, and which may be pressed out, so that the foetal lung will sink, which can never happen when the lungs have been distended by natural breathing or insufflation.

A general presumption only can be drawn from the consistence of the lungs. If they are soft and have a regularly vesicular appearance, respiration either natural or artificial must have taken place, and a reference to the other tests of independent life will show which of the two has happened.

3. *Specific gravity*.—It was known to Galen that the foetal lung sank in water, but that after respiration it floated, and these facts form the foundation of the hydrostatic test. Swammerdam affirmed that the lungs would float if only one inspiration had taken place, in which assertion he has been followed by Haller, Daniel, and Dr. W. Hunter.

But subsequent experience has shewn that the specific gravity of the lungs before and after birth does not observe an uniform ratio. It has been ascertained, first, that newly born children may live some time without respiration; secondly, that after respiration has been carried on for some time, the lungs are not

uniformly dilated, and occasionally to so trifling an extent only, that they sink in water, or sometimes that the lungs are unequally dilated or diseased; and thirdly, that in some still-born children the specific gravity is less than that of water, which may arise from breathing before complete birth, from artificial inflation, or extrication of air through other causes; and objections to the conclusiveness of the hydrostatic test have been alleged for these several reasons.

a. It is a fact familiarly known to all obstetrical practitioners, that children occasionally do not breathe till they have been born for some time; but there are no means of determining whether a child found dead could have been animated had the proper measures been resorted to. And the proof that a child so circumstanced had been murdered must rest on the evidence of existing mortal injuries, which it was morally impossible could have been the consequence of accident, but must have resulted from criminal violence. In short the evidence of murder in such a case must be similar to the proofs of infanticide during parturition.

b. But the lungs may sink, although the child have breathed for some time, owing to their imperfect dilatation. Craanen* described it as a frequent occurrence, and had the merit of pointing out how the fallacy might be obviated. He recommended that each lobe of the lungs be cut into small portions and thrown into water. If all sank, he inferred that the child died in utero; but if a few fragments floated, he concluded that the child had survived delivery. The imperfect dilatation of the lungs after respiration has been usually found in immature children, but cases have been related by Schenkus, Bernt, and others, of children born at the full time, and who had lived one or more days, whose lungs sank in water; and we recollect an example of the same kind which occurred to the late Dr. William Cullen of Edinburgh. The proceeding recommended by Craanen is, no doubt, applicable to all such cases; and the conditions of the ductus arteriosus Botalli and pulmonary arteries, to be hereafter noticed, would, in conjunction with other proofs, remove all doubts concerning the conclusiveness of the hydrostatic test in similar instances.

c. A diseased condition of the lungs may also prevent their floating after respiration, but it is extremely rare to find the foetal lungs in such a state of disorganization as to admit so little air that the whole lung will sink in water. Such a pathological state must be quite conspicuous, and the proceeding recommended by Craanen would easily obviate the fallacy, for if life had been maintained at all, some portion would float.

have related examples of lungs which have sunk from congestion of blood in consequence of suffocation. The best informed pathologists, Meckel for instance, have doubted the possibility of such an occurrence, but the fact has been attested by the three authors just named. This is an objection to the hydrostatic test easily corrected, for after gently pressing out the blood, the lung will float. Thus, although the lungs may sink in a child which has outlived birth, the circumstances under which this may happen are known, and can be readily detected and allowed for.

It has been farther observed that the lungs in children notoriously still-born will sometimes float, and the circumstance has been adduced as a ground of objection to the hydrostatic test. Such floating has been ascertained to depend, first, on breathing before delivery, the child nevertheless dying before complete expulsion; and secondly, the lungs may be rendered specifically lighter than water by artificial inflation, by putrefaction, or by a species of emphysema, first noticed by Schmidt,* and subsequently more distinctly characterized by Chaussier.†

e. The possibility of uterine respiration was denied by all writers down to the time of Bohn.‡ He first maintained, in 1700, that in *difficult labours* a child may draw in air enough to suffice for the distention and floating of the lungs, and yet die before delivery. Bredenoil has related a remarkable example in Siebold's *Journal für Geburtshilfe*, Band I. It was a case of twins; the first child had been delivered by the forceps, the membranes ruptured, and the hand introduced to turn the second, whom he heard distinctly to cry for at least a dozen times. Bernt has mentioned four somewhat analogous cases. In a child delivered by turning and destruction of the brain, every fragment of the lungs floated.§ Of the other three cases, two fetuses were extracted after the mother's death, the vagina in the one and the neck of the womb in the other having been ruptured; and the third was extracted by the forceps on account of tedious labour. In these the lungs sank when entire, but many fragments floated, and in all the four examples every other test coincided with the hydrostatic to justify the inference that the children had respired. Until recently the evidence in favour of uterine respiration had been altogether supplied by German authorities; lately, however, Professor Marc has recorded an unequivocal example of the kind communicated to him by M. Henry, which has removed the scepticism formerly entertained on the subject by the learned professor, and others also we presume. A woman, having a deformed pelvis, and pregnant for the third time, was in labour on the 10th of October, 1827. M. Jobert was in attendance and called in M. Henry to his assistance. Having ascertained that the de-

formity occasioned an obstacle to delivery, M. Henry observes,*—"M. Jobert and I thought that it might be necessary to turn the child, but as the head did not appear to be very voluminous, we hoped to be able to disengage it by means of the forceps. That instrument was applied; and as soon as M. Jobert commenced the attempts at extraction, the fœtus uttered repeated cries during a dozen seconds, so distinct as to be heard by all the assistants. But as the head remained impacted in the pelvis, notwithstanding the efforts made with the forceps, we were obliged to desist from this attempt.

"Whilst we were discussing the necessity of turning the child, these cries were renewed as distinctly as on the former occasion, and in such a manner as could only take place in consequence of repeated inspirations. Finally, when introducing my hand to seize the feet, the moment it passed over the left shoulder the fœtus for the third time uttered cries, less prolonged than the preceding, yet sufficiently loud to be heard by all present.

"The delivery was completed with much difficulty, and the child did not breathe after its expulsion; but as the pulsations of the heart were pretty strong, we tried various means to resuscitate it, among others insufflation of the lungs. Our attempts were fruitless, for at the end of some minutes the circulation had ceased. I regret that I cannot describe the state of the lungs, but as insufflation was practised, an examination of them could not have afforded precise and unexceptionable information."

But the case now to be related proves incontrovertibly that these cries may be uttered by a child in utero, and subsequently born alive without assistance. It is described by Dr. A. F. Holmes, Lecturer on Chemistry and *Materia Medica*, McGill College, Montreal.† "On the 29th of November, 1828, I was called to a lady in labour of her sixth child. The fontanelle presented, but the pelvis being capacious, and her labours generally easy, no attempt was made to change the position. The head continuing to descend, the mouth lay on the pubis, and the examining finger could easily be introduced into it. The occiput did not yet occupy fully the cavity of the sacrum. At this time I heard sounds like the cries of a child whose mouth was muffled by some covering, but not being very distinct, and not being at all prepared for them, I thought, when they ceased, that they must have been produced by flatus in the intestines of the mother. In the course of a short time, however, the cries were repeated, and with the greatest distinctness, so as not to admit of a doubt that they proceeded from the child. The mother, much alarmed, enquired the cause of these noises, and required to be assured that they were not indicative of any danger. The pains being brisk, the head was soon forced down and expelled. The child was a female,

and is still (August, 1829) alive and thriving."

The evidence for vaginal respiration is equally conclusive. Formerly Professor Marc* endeavoured to shew that, from the compression of the foetal thorax in the passages, it was impossible; but his reasoning must yield to the unquestionable testimony of Schmidt, Oslander, and Capuron, each of whom has witnessed it. In relation to infanticide it has been usual to disregard the vagitus vaginalis, as occurring only under circumstances which could not lead to doubt in the decision; either because it was only heard after the expulsion of the head when there could be comparatively but little difficulty on the part of the mother, and as little danger to the child in the accomplishment of complete expulsion; or that it occurred in presentations of the face and feet, in which delivery could not be completed without great difficulty or foreign manual assistance, and was therefore not likely to occur in medico-legal practice.

The experience of practitioners will not completely justify this view. It is undoubtedly for the most part true, that when the head is expelled, the complete birth of the child is attended neither with difficulty nor danger; but the case related by Dr. Hosack† proves that a child *may* perish after the expulsion of the head and before complete delivery, and that in the interval it may breathe and cry. The editors of the London Medical and Physical Journal‡ have observed a similar occurrence; and every practitioner of experience must have met with presentations of the face and feet, in which delivery has been completed by the unassisted expulsive efforts of the uterus.§

Uterine and vaginal respiration appear therefore to constitute a possible objection to the determination of the life of the child after birth, which may sometimes be insuperable. The correct objection to oppose to it, is the rarity of such a conjunction of circumstances as is indispensable for the occurrence; and the full expansion of the lungs, if present, would render such a plea more than doubtful.

The lungs may float from insufflation or artificial respiration, and Bohn|| and Camper¶ have quoted instances in which it had been successfully practised by blowing air into the lungs with the mouth. Schmidt** has investigated the subject of artificial respiration, and established the facility with which it may be practised. According to his experiments crepitation is always present, and the distention of the thorax is permanent, but the ratio of the weight of the lungs to the rest of the body remains as in dead-born children. The results of the *static* test, the colour of the lungs, and

the unaltered conditions of the ductus arteriosus Botalli and pulmonary arteries would distinguish insufflation of the lungs in a dead child from respiration, either natural or established artificially in a living one.

It is impossible to conceive, however, that a woman charged with infanticide, who had attempted to resuscitate her child by insufflation, could fail to produce satisfactory proofs of her innocence; for it may be reasonably presumed that a child subjected by a mother to such an attempt would not exhibit any signs of criminal neglect or wilful ill-treatment, whilst the attempt to inflate the lungs would form a presumption in favour of the accused. Morgagni* and Dr. W. Hunter have suggested that insufflation may be practised by another person from a malicious motive towards a mother; but were such an apparently incredible occurrence to happen, the results of the other indications of life would demonstrate by what means the lungs had been expanded.

"Medical jurists," says M. Devergie,† "have endeavoured to represent the inexperience of drawing positive conclusions from the evidence under consideration, by alleging that a woman may have inflated the lungs of her own child for the purpose of restoring it to life; or that another person may have done so from a criminal motive towards the mother. Such observations are just; but a multitude of cases occur where the circumstances in which the body of the child and the author of the crime are found, totally exclude them from consideration. For example, a child has been thrown alive upon the ice of the Seine, undoubtedly *living* at the time, for it presents all the signs of injury which can result from such a fall; another is found in the water, inclosed in a bag firmly sewed up; a third is thrown into the street, the mouth and pharynx filled with linen, so as to produce suffocation; a fourth floats on a river inclosed in a paper box, and so enveloped in linen as to prevent the access of air; a fifth has been thrown into a privy; a sixth dismembered and buried in an unfrequented situation. Certainly none of these proceedings could have been the act of a mother who had practised insufflation in order to restore her child to life, nor could it be attributed to a person, who, having wickedly simulated a crime, would have an obvious motive in proclaiming its apparent existence."

An objection to the hydrostatic test has been drawn from the putrefaction of the lungs, and the consequent floating from the air thus disengaged. Although this is an objection of very little practical importance, it has occasioned much controversy. Heister,‡ in 1722, observed the lungs of a child which had died in the womb, to float both whole and in pieces, and the known circumstances of the case proved that insufflation could not have been

practised. Haller* instituted experiments on the subject. He allowed the lungs of a dead-born child to become putrid in water, and saw them float after seven days in the same water. The colour was changed from dark to light red, and they were covered with air-bubbles. A dark-red compact-feeling lung out of another body, already powerfully offensive, sank both entire and in pieces. He concluded, therefore, that considerable putrefaction was necessary to cause the floating of the lungs. Camper had previously made the same remark, and had found that, when the whole body was so far advanced in putrefaction that the joints separated with the slightest touch, the lungs had only begun to decay, and would not float in water. Jaeger, from experiments and observations on the difference between sound and putrid lungs, drew the following conclusions: a lung which floats from putrefaction is distinguished from one which does so from breathing, by the situation of the former against the spine, by its dark-red colour, and by the air being found under the outer membrane in the form of bubbles,† and by the easy escape of the air after cutting into the lungs and the subsequent sinking of them. The air developed by putrefaction he found to escape with much facility by means of incisions and gentle pressure; not so in those which floated from respiration. Mayer‡ also engaged in an extended series of experiments on the putrefaction of the lungs. He found that, on placing the lungs of still-born children in water, in the course of two or three days their colour changed, and they increased in volume. By the eighth day at latest they floated, both whole and cut into pieces, in the water in which they became putrid, but, transferred to clean water, although they still floated, yet on the slightest compression they sank. The rays of the sun accelerated the putrefaction, but a current of air retarded it, so that they did not float until the tenth or eleventh day. After having once floated, they continued to do so, emitting daily a more offensive odour and acquiring an increased volume, until the twenty-first or at latest the thirty-fifth day. After that period they gradually sank down, without a single exception, to the bottom of the vessel, nor did they afterwards in the least float, although kept for seven weeks or even longer. Beck§ and Orfila have confirmed these results of Mayer, to which M. Devergie has added the following interesting practical correction. Referring to the above experiments, M. Devergie observes:¶ “Although the above experiments appear incontestible, an accidental circumstance may completely change their results, so true is it that practical deductions drawn from experiments are frequently liable to error. In the number of the *Annales d'Hygiène et de*

Médecine Légale for Oct. 1830, I published two cases of infanticide submitted to my examination, in which putrefaction of the lungs with development of gas was evident. The children had been thrown into the Seine, remained in the water seven or eight days, and subsequently exposed to the air from twenty-four to thirty-six hours before being opened.

“It is ascertained that, whenever a person drowned is taken out of the water after having been submersed for ten or fifteen days, if the temperature of the atmosphere ranges between 15° and 25°, a considerable development of gas takes place in the body immediately on its exposure to the air. In consequence of this disengagement of aeriform fluid, which takes place not only in the subcutaneous tissue, but even in the internal organs most protected from the agency of the atmosphere, the fluids of the body are conveyed to the surface, bullæ are formed, sanies exudes from the cutaneous pores in general, and escapes also by the natural openings. In a great number of bodies the development of putrid gas is so considerable as to effect an alteration in the posture of the limbs, and even to change the general position of the body. Thus, it has been found necessary to secure the bodies, publicly exposed at the *Morgue*, to the tables on which they are placed. Before this precaution was adopted, the bodies occasionally fell to the ground; and strangers frequently hastened to inform the porter that an individual placed there was not dead, for they had seen him move.

“The phenomena observed in the body of an adult found drowned, develop themselves with equal or greater rapidity, under the same circumstances, in the fœtus. Now it is very rare that a medico-legal examination of a body takes place, before the *procureur de roi* (in England the coroner) has been informed of it; hence at least twenty-four hours generally elapse, during which period the body is undergoing the changes indicated above, and the lungs become as emphysematous as possible.”

We have said enough, however, to shew that air developed in the lungs by putrefaction must be an extremely rare event, that it is easily recognized, and any fallacy arising from it readily avoided.

Alberti* in 1728 threw out a hint that the lungs sometimes contained air which was derived neither from putrefaction nor respiration. In 1806, Schmidt† confirmed the observation, remarking that bubbles of air appear in the lungs which do not betray the least trace of putrefaction, and that they are thereby rendered capable of floating. The same phenomena occurred to the observation of Chausier,‡ who suggested the following method of obviating the fallacy: “In these instances,” says he, “the aeriform fluid is contained in

the cellular tissue of the lungs, whence it may be expelled by pressure, after which the lungs thrown into water immediately sink. This does not happen if the air was contained in the minute air-cells."

The preceding observations include all the objections alleged against the conclusiveness of the hydrostatic test as a proof of extra-uterine life. If we except the rare and barely possible occurrence of uterine or vaginal respiration, it must be evident to every candid mind that these objections possess neither conclusiveness nor force; and that the circumstances on which they depend can be so easily and fully appreciated as to avoid any error which could lead to the crimination of the innocent. Of the considerations to be opposed to the *vagitus uterinus* we have already spoken, and shall again advert to them before the conclusion of this article.

4. *The difference between the weight of the lungs before and after natural respiration.*—This constitutes the *static test* first proposed by Ploucquet* in 1777. Experience, however, soon shewed that this test was limited in its practical application, since, in some children who had lived several days, the weight of the lungs proved to be less than that frequently observed in still-born children. It was, therefore, suggested to substitute as a criterion, the *relative* weight of the lungs, before and after natural respiration, to the whole body. But the experiments and observations of Chaussier, Schmidt, and Bernt, have shewn the inutility of this modification of the static test, by pointing out that in many still-born children the ratio was a lower one than the average for children who have breathed, and vice versa. Schmidt, seeing therefore that this method was not an improvement, proposed to return to the original mode of judging by the *absolute* weight of the lungs, and to confine the application of the static test in this form to those cases in which the weight is such as is never attained by the natural and healthy *fœtal* lung. In twenty-four still-born children examined by Bernt,† the greatest weight of the healthy lungs was 993 grains, and he states the medium at about 550 grains. The form of the static test recommended by Schmidt is very limited in its application for the lungs of children who have outlived delivery; not more than one in six or seven equal the former weight. When the *fœtal* lungs, being naturally formed and of healthy structure, exceed 1000 grains, such weight may be considered as constituting decisive proof that the floating of the lungs and their loose and expanded appearance do not result from insufflation practised on a dead child, but must be a consequence of the continuance of respiration and of the circulation

of blood through them, and therefore of life; and even if the weight exceed in any considerable degree 550 grains, the same inference is a reasonable presumption.

5. *Size of the lungs.*—As respects the volume or circumference of the lungs, it is observed by Bernt* that naturally formed and healthy *fœtal* lungs which have not respired, occupy the posterior part of the thorax, merely touching the pericardium with their anterior borders. The posterior half only of the arch of the diaphragm is covered with them: the edges are sharp, the margins of the right, middle, and left upper lobes forming small pointed, tongue-shaped elongations. If, however, the child have lived a very short time after birth, and breathed only imperfectly, the lungs are found to occupy the lateral parts of the thorax also; their anterior borders and the tongue-shaped elongations of the right, middle, and left upper lobes are become round either partially or altogether. After full and complete respiration the lungs entirely fill the lateral cavities of the thorax; their anterior borders cover the sides of the pericardium, and their concave surface the whole arch of the diaphragm; their borders are every where rounded, and the tongue-shaped prolongations of the right, middle, and left upper lobes are short and obtuse.

6. *State of the ductus arteriosus.*—Passing over the changes which take place in the foramen ovale, the ductus venosus, and umbilical vessels, changes which take place at too late a period after birth to supply satisfactory evidence in trials for infanticide, we come to the consideration of the comparative state of the ductus arteriosus Botalli, and the branches of the pulmonary artery before and after respiration. Previous to the investigation of Bernt no minute observations had been made on the changes which these vessels undergo soon after delivery. It might have been anticipated that the occlusion of the ductus arteriosus must be rapid, since its perviousness would form an impediment to the perfecting of the child's new mode of existence, but it had not occurred to medical jurists to seek for any indication of extra-uterine life from this source.

In the *fœtus* the ductus arteriosus proceeds from that part of the trunk of the pulmonary artery where it divides into its two great branches, and running parallel with the arch of the aorta and in contact with it, joins it at a very acute angle. It is about half an inch long, cylindrical, equal in diameter to the trunk of the pulmonary artery, and almost three times the diameter of its two branches, each of which branches is about the thickness of a crow-quill.†

If the child, says Bernt, have breathed for a few moments only, the aperture by which the duct enters the aorta becomes oval; if a little longer, it loses its cylindrical form, and

* Abhandlung über gewaltsame Yodesarten, L. 153-156.

† Experimentorum Docimasiam, &c. Edinburg Medical and Surgical Journal, p. xxvi. p. 375. Handbuch der gerichtlich. Arzneikunde, u. s. w. von J. Bernt, Wien, 1828, s. 256.

* Handbuch, 266.

† Experimentorum Docimasiam, &c. Proleg. p. xiv. Handbuch, 277.

assumes the shape of a cone, the apex being at the aortal end, but sometimes, though much more rarely, at the opposite extremity; the diameter is diminished so as to be smaller than that of the trunk, but about equal to that of the two branches of the pulmonary artery, the latter, owing to the establishment of the pulmonary circulation, having already increased in diameter.

If the child have lived for some time, and breathed perfectly, the ductus arteriosus Botalli resumes the complete cylindrical form, but has become shorter, and is not thicker than a crow-quill, whilst the two pulmonary branches are thicker than a goose-quill. As these comparisons are determined by the relative size of objects situated close to each other, an observer would not be liable to fall into error, as he is otherwise apt to do in estimating relative magnitude.*

The observations and experiments on which the preceding inferences relative to the blood-vessels are founded, were made previous to the year 1823; and in the Manual of Medical Jurisprudence published in 1828, Professor Bernt adheres to the same conclusions, and informs us that they have been confirmed by the observations of Kilian,† a writer of authority on the fetal anatomy. As we have attentively examined these observations and experiments, which are seventy-five in number, and not been able to concur with Bernt in his inferences in every particular, we shall briefly state those which appear to be conclusive, and of practical application in medico-legal inquiries.

In every instance of respiration, whether naturally accomplished or the effect of resuscitation from insufflation, a general or partial diminution of the diameter of the ductus arteriosus was found. But a diminution in general diameter (so that the natural relative diameter between the ductus arteriosus and the trunk and branches of the pulmonary artery did not exist) was sometimes found in children notoriously still-born, and who had not breathed artificially; hence a smaller relative diameter of the duct cannot be relied on as a proof of extra-uterine life. But the contraction of the extremity (either aortal or otherwise) of the duct, though sometimes absent in children who had respired, was never present unless respiration had been carried on; so that, if the ductus arteriosus represent a cone in figure, it may be regarded as a decisive indication of the continuance of the pulmonary circulation, and hence of breathing.

Having now investigated the evidences of independent life, which may be supplied by the examination of the body of a child found dead, we proceed to arrange the inferences of practical value in a compendious form. The state of the stomach, bowels, and urinary bladder, and of the umbilical cord, has been

purposely omitted, as in a large majority of cases they do not furnish any indications which can be relied on.

First.—A child may be concluded to have been still-born who does not present the signs of having arrived at the sixth month of uterine life: or

The colour of whose lungs is uniformly dark-red, or verging towards the brown-red of the liver or bluish-red of the thymus:

If they are of a fleshy compact structure, somewhat like liver, presenting no traces of cells on the surface, nor yielding a crepitating sound when cut, nor bubbles of air when portions of them are pressed beneath the surface of water:

If the whole lungs and every fragment when they are cut into small pieces immediately and rapidly sink in water; and when the weight of the whole lungs (being naturally formed and healthy) is below five hundred grains:

If the lungs have occupied the posterior cavities only of the thorax, merely touching the pericardium with their anterior borders, and covering with their concave surface the posterior half of the arch of the diaphragm, the edges being sharp, and the margins of the right, middle, and left upper lobes forming small tongue-shaped elongations: and if the ductus arteriosus is cylindrical throughout, being of equal diameter with the trunk of the pulmonary artery, and two or three times the diameter of the two pulmonary branches.

Secondly.—It may be concluded that a child has lived a short time and breathed imperfectly,

Whose lungs being for the most part dark-red, brownish, or bluish-red, present, here and there, in one or both lungs, but particularly on the edges, insulated scarlet or cinnabar-red spots or streaks; when there are visible, particularly in the upper lobe and edges of the right lung, insulated groups of cells surrounded by portions retaining the compactness of liver; when this cellular portion yields a crepitating sound on being cut, and bubbles of air if pressed under water; when the lungs occupy more or less the lateral cavities of the thorax, and their margins, particularly the prolongations of the right middle and left upper lobes, are partially or altogether of a rounded form:

When the lungs, with or without the heart, sink in water, but some fragments of them, when divided, float, even after having been subjected to pressure; and when the absolute weight of the lungs much exceeds five hundred grains:

If the ductus arteriosus is smaller in diameter than the pulmonary trunk, and about equal to the pulmonary branches, and particularly if with these signs it is contracted either at the aortal or other extremity, so as to assume a somewhat conical shape.

Thirdly.—A child may be concluded to have lived for some time and breathed perfectly,

If the lungs are of a pale red colour gene-

* Edinburgh Medical and Surgical Journal, vol. xxvi. p. 378.

† Abhandlung über den Kreislauf des Blutes im Kinde welches noch nicht geathmet hat. Karlsruhe, 1826.

rally, but with numerous spots and streaks of scarlet; the posterior surface only being dark red, in consequence of the gravitation of the blood to that part:

If the lungs completely occupy the lateral cavities of the thorax and cover the sides of the pericardium, and if their lower concave surface cover the whole arch of the diaphragm, their edges being every where rounded, and the tongue-shaped elongations of the right middle and left upper lobes short and obtuse: if insulated groups of innumerable cells distended with air are visible with the naked eye in the substance of the lungs; if they are every where expanded and spongy in texture, crepitating audibly when cut, and yielding, on pressure under water, numerous bubbles of air or bloody froth:

If the lungs connected with the heart, or separated from it and each separate lobe, project above the surface of the water, and every fragment, when they have been divided and subjected to strong pressure, float; and if their absolute weight exceed one thousand grains:

And if the ductus arteriosus is short and much contracted in diameter, so as to be as small as or smaller than the branches of the pulmonary artery; or if it be decidedly contracted at the aortal or other extremity, so as to represent in form a truncated cone.

To every indication, hitherto adduced, of the extra-uterine life of the child, the possible occurrence of uterine or vaginal respiration presents an objection which deserves farther consideration. In the preceding remarks we have adverted to cases of this kind, which refute the opinion hitherto entertained that this species of respiration cannot come in the way in medico-legal investigation, because it can only occur in cases requiring instrumental or, at least, foreign manual assistance. Although there can be no doubt of the general correctness of this opinion, it is manifestly not true in all instances; for the cases of Dr. Hosack and Dr. Holmes* prove that it may be met with in instances of delivery capable of completion by the natural efforts only.

Admitting, however, the possibility of intra-uterine and vaginal respiration, we must contend on the other hand for the extreme rarity of the occurrence; so rare, indeed, that, until very recently, it has been regarded with the greatest distrust by European practitioners in general with the exception of the Germans; and it is doubtful whether any other positive evidence than that recorded in the present essay, exists in the writings of French and English authors in its favour. Ought, then, so rare an occurrence to be admitted as a decisive reason for uniformly rejecting the conclusiveness of the indications of life which we have hitherto been discussing? We think not, and doubt extremely whether the signs of *perfect* respiration which we have just detailed are ever to be met with in such cases; whilst we have every reason to believe that they are commonly found in the bodies of children

who have died from criminal violence or neglect.

Vaginal respiration may occur in natural presentations, but the delivery in such a case must be *delayed* to admit of it, and thus the labour would become "difficult." In every such case the tumour of the vertex would plainly indicate its nature. Face presentations, in which vaginal respiration may occur, are capable of proof from the absence of the tumour just named, and from the tumid and distorted features; and footling presentations are recognizable, if death have taken place soon after birth, by signs not difficult of detection. Such are the cases most favourable to the possible occurrence of vaginal respiration; and although they demand full consideration, they seem nevertheless capable on careful inquiry of tolerably easy detection. Should there be no proofs of difficult labour, whilst indications of full and complete respiration are found, and conjoined with these there exist signs of fatal injury, which could not have been accidental, and must have been inflicted during the continuance of the circulation, the proofs of infanticide would be indubitable; for to reject them would be to disallow the force of the strongest circumstantial evidence.

II. In proceeding to inquire into the *cause of the death of the child*, we may remark that it may have died in the womb previous to the commencement of labour; or during the act of parturition, or after birth; and in each case death may have been produced by natural or criminal causes.

1. The death of a fetus in utero criminally induced in the early periods of utero-gestation, falls under the head of criminal abortion; at a later period death arises most frequently from natural causes, from disease in the mother, in the fetus itself, or in the secundines; but it may result from premature labour brought on artificially by puncturing the membranes.

A fetus having died in utero, may remain there an indefinite time, and even be converted into adipocere. Generally it is expelled from five to twenty days, exhibiting unequivocal signs of putrefaction; the members are relaxed, the muscles flabby, the epidermis detached by the slightest touch, the skin is of a purplish or brownish-red. Frequently there is a sanguineous or serous infiltration of the whole subcutaneous tissue, particularly under the hairy scalp. The umbilical cord is thick, soft, brittle, and infiltrated. The chest is sunken or flattened. The head is deformed, falling flat by its own weight; the pericranium and dura mater are separated from the bones, which are nearly, if not altogether, disunited, and the cerebral substance is converted into a putrilaginous mass. Jaeger observes that these signs are quite peculiar, and that their concurrence distinguishes this state from death by injury, and every thing else.*

* See page 686.

* Schlegel, "Opuscul. Collectio V. 48. Lecieur.
2 y 2

2. Capuron,* who has given the best summary of the causes of death during parturition, has divided them into innocent and criminal.

Of the former kind are difficult labour with premature evacuation of the liquor amnii; total or partial separation of the placenta; premature expulsion of the funis; presentation of the feet; detention of the body from malposition after the expulsion of the head; and the "entortillement," or turning of the funis around the neck of the child.

The effects on the child of difficult labour with premature evacuation of the liquor amnii, are such as result from severe and continued pressure; and the death of the child takes place in the way of apoplexy. The signs which indicate it are the *séro-sanguineous* tumour of the vertex; if the head have presented, deformity and elongation of the head, attended even with fractures of the bones, tearing of the membranes, or separation of the pericranium and effusion under it.† The position of the injuries of the head, and the absence of any distinct sign of impingement from a bruising body, combined with the absence of the signs of respiration, would satisfactorily elucidate these phenomena.

In the case of total or partial separation of the placenta, the death of the child is of course from hemorrhage, and the body would present the signs of *anæmia*. It might be confounded with death from hemorrhage from the umbilical cord; but the absence of the signs of respiration would be a decisive means of discrimination. The mother would also present signs of *anæmia*.

In premature expulsion of the funis, the death of the child is from asphyxia. No sign of injury would be present, nor would there exist any proof of respiration.

Presentation of the feet, with all but the head expelled, and the delivery tedious: in such a case a woman might assist herself, and in so doing inflict so much injury on the child by her injudicious attempts, as to excite strong suspicion against herself; and the more particularly, as this is a conjunction of circumstances under which vaginal respiration may occur. Such a case would require a circum-spect observation of all the particulars; but there are circumstances which could scarcely fail to lead to its correct elucidation. The indications of difficult delivery and of the presentation of the feet would be easily observed, and an examination into the situation and nature of the injuries would show whether they were of a kind which a woman might be expected to inflict on her child in promoting her own delivery. If death were not the result of injury, it would take place in the way of apoplexy, and the corresponding signs would be found.

In retention of the body from malposition or otherwise after the expulsion of the head, death results from asphyxia, from the com-

pression of the funis, if the child have not breathed; and if it have, from impediment of the free expansion of the thorax. In the former the absence of the signs of respiration, with the want of proof of criminal neglect or violence, would rebut the charge of infanticide; in the latter, imperfect respiration would be recognised by its appropriate indications, the severity of the labour would be proved by the tumour of the vertex and other signs, and the want of proof of criminal act or intention would render the charge of murder untenable.

The only other innocent cause of death during parturition deserving of particular attention is the "entortillement" or turning of the funis around the neck of the child. If this circumstance lead to fatal consequences, it is either by inducing apoplexy or asphyxia, according as respiration have or have not been carried on. Should any sign of injury be left, it will consist of a spiral impression, or (if the cord have passed round more than once) of the circular and spiral line discoverable on the neck. The epidermis is never puckered, nor the cartilages of the trachea injured. If it were alleged that the cord have passed round the neck more than once, it should be ascertained whether it was sufficiently long for that purpose.

It is proper to add that fractures of the bones sometimes take place in the uterus, of which Chaussier* has related a remarkable instance. In this example each of the long bones presented one or more fractures, some of which were recent, others beginning to unite, and others had united.

The criminal causes of death during parturition are various, and for the most part evidently betray the intention with which they were employed. They almost always imply the aid of an accomplice, and hence are of comparatively infrequent occurrence. Of these the following are the most usual:—puncture of the brain through the fontanelles or sutures, or of the spinal marrow between the first vertebra and the occiput; torsion or compression of the head; detraction; strangling and suffocation.

Belloct† has reported an instance of child-murder in which the brain was punctured through the anterior fontanelle. The external wound did not exceed half a line in length. On examination it was discovered that it penetrated the brain to the depth of two inches. At this point the cerebral substance was lacerated in several directions. Blood was effused both between the membranes and in the left lateral ventricle. Gui-Patin, Alberti, and Brendel have cited similar examples; and in the article *ACUPUNCTURE* in this *Cyclopædia* reference is made to a trial in the "*Causes Célèbres*" for the same horrible offence. It is doubtful, however, whether these means

* *La Médecine Légale relative à l'art des accouchemens.*

† *Fodéré*, iv. 503.

* *Bulletin de la Faculté de Médecine*, tom. iii. See also Otto's *Handbuch der Pathologischen Anatomie*, 394.

† *Cours de Méd. Lég.* 101.

would prove so rapidly mortal as to destroy life before the expulsion of the child. In the case related by Belloc, death appeared to have been produced by suffocation, the laceration of the brain not having been effectual.

In torsion of the neck the injury inflicted on the spinal marrow might be immediately fatal. The marks of violence presented by the ligaments of the vertebræ and neighbouring muscles would indicate the nature of the case; and it is highly probable that the marks of the pressure of the fingers would be visible.

Foderé* has related the trial of a widow who destroyed her child in the act of parturition by compressing its head between her thighs till it was dead.

It is doubtless possible that a child may be strangled or suffocated before complete respiration has taken place; but the nice accomplishment of such a purpose requires a more refined application of injury than is almost ever practised; and without such caution the remains of intentional injury would be demonstrable. If strangulation were attempted whilst the circulation was proceeding vigorously between the mother and child, continued pressure would be necessary for its accomplishment, as death would take place in the way of apoplexy; and for such continued pressure a longer intermission of uterine pain would be required than is usually found to occur.

3. The causes of death after delivery are natural or criminal; and the latter are subdivided into those which are fatal by omission and by commission.

The following is a general summary of the natural causes of death after delivery:—immaturity, disease, malformation; omission of the usual and necessary attentions; injuries from severe labour or from sudden expulsion; sudden and simultaneous expulsion of the placenta, and consequent hemorrhage; prevented respiration from envelopment in the membranes; or suffocation in the discharges. The two causes last enumerated are not distinguishable from the same causes of death intentionally applied. Of the others, injuries from severe labour and from sudden expulsion are most likely to be confounded with the effects of criminal violence, and hence demand the most careful and deliberate examination. With reference to the former, it should be recollected that “fluid blood effused at the base of the brain is met with in all children, when the head has been long in the pelvis, and the child has died in that situation.”† The cerebral ventricles of newly born children, Foderé adds, usually contain much reddish serum, and the brain much blood. And when the superior aperture of the pelvis is narrowed by deformity, even fractures of the bones may occur with depression of them into the brain. But all these effects require for their production a disproportion between the size of the head and dimensions of the pelvis. The state of the

former should indicate the difficulty of the labour by its deformed and elongated appearance, and by the unusual size of the sanguineous tumour at the vertex. Signs of laceration and contusion ought not to exist.

Injuries arising from sudden expulsion are very rarely fatal, or even dangerous; and they are less likely to be confounded with the causes of infanticide, inasmuch as they are of infrequent occurrence in first labours, on which occasions the crime is for the most part perpetrated. No instance of the death of a child from sudden expulsion has come within our knowledge. Suffocation in privies under such circumstances is of course possible, and Hutchinson* says instances are reported; he has not, however, supplied any reference to them. Several years ago Chaussier† experimented on dead children to ascertain the effects of falls from a given height, and also of blows, on the cranium. These experiments, neither very refined nor conclusive in their character, are superseded by the more recent observations of M. Klein‡ of Stuttgardt. M. Klein, taking advantage of his situation of Member of the Superior Council of Health, caused a circular to be addressed to the midwifery practitioners of the kingdom of Wurtemberg, requiring reports of the cases of sudden expulsion of the fœtus which might be observed by them. Returns were made of one hundred and eighty-three cases. Of these, one hundred and fifty-five children were expelled whilst the mothers were in the upright posture, twenty-two when sitting, and six when on the knees. Twenty-one happened at the first labour. Of the whole number not one child died; no fracture of the bones took place, nor any other severe injury. Two only suffered temporary insensibility, and one an external wound with sugillation over the right parietal bone. Not one suffered from umbilical hemorrhage, although in several the cord was ruptured at four, three, and two inches, and even one inch from the umbilicus. In twenty-one children it was torn off close to the abdomen, yet no serious hemorrhage followed. We are entitled, therefore, to conclude that in accidents of this kind the death of the child, if not impossible, is highly improbable; and if it should occur, we have no reason to think that it would be immediate.

The criminal causes of death by omission are, the neglect of removing the child from under the bed-clothes, or from the state of supination; the want of suitable warmth; neglect of nourishment; and the neglect of the ligature of the umbilical cord.

Death has resulted not unfrequently from the first of these causes; but the medical man possesses no peculiar means of determining whether this has happened from design or from the mother's inability to render the usual succours. Dr. William Hunter has mentioned

* Vol. iv. p. 524.

† Foderé, iv. p. 503.

* Dissertation on Infanticide.

† Lecieux, op. cit.

‡ Dict. de Médecine, tom. xii. p. 188.

a case which shows how readily neglect of this kind may prove fatal.

Death from want of suitable warmth, which is almost always conjoined with public exposure, is proved by the evidence of respiration and circulation; by sanguineous congestion in the large vessels, with comparative absence of blood in the superficial ones; by the position of the body; and most conclusively perhaps by the *cadaveric congestion or lividities** which are met with in the depending parts of the body.

Neglect of nourishment is also generally combined with public exposure; under which circumstances death may be attributable to the combined causes. It would be very difficult to prove the death of a newly born child from neglect of nourishment only, because to establish that it would be requisite to show how long the child had lived, which there are no means of determining with strict accuracy. The changes supervening in the umbilical cord would furnish the best evidence; and being applicable on other occasions, we shall describe them in this place.

The umbilical cord varies in different children considerably:† in some it is slender and comparatively firm, in others thick and soft; the thickness varying from the greater or smaller quantity of the albuminous fluid, called the gelatinous fluid of Warton. The changes which take place in the cord are, first, flabbiness, then dessiccation, and lastly separation from the abdomen; and all these processes occur at different periods of time in different children, according to the thickness or thinness of the cord. Immediately after birth, or at farthest in a few hours, the flabbiness commences, and it is complete in the course of a day, or at most in two days. Dessiccation, which commences after the fading of the cord is complete, begins generally at the end of the first day, and is completed on the fourth or fifth, when the separation takes place. The dessiccation is a purely physiological phenomenon, for it does not take place in children born dead; in them the cord remains soft and flexible, and then becomes putrid. The dessiccation of the cord is more speedy when it is thin; and it is rare that separation of a slender funis is attended by suppuration, or even inflammation. When it is thick, the case is otherwise; suppuration at its junction with the abdomen takes place, with a red and thickened base. The slowness of the separation appears to occasion the inflammation.

A consideration of these circumstances will indicate the age of a child approximatively within the first four or five days after birth.

The neglect of the ligature of the umbilical cord may be accidental or intentional. The absence of it is unfavourable to the accused, and more particularly if the funis be cut. The effects of the absence of the ligature of the umbilical cord have been a fruitful source

of controversy; many, Capuron among others, having doubted whether fatal hemorrhage could result if the ligature were not applied.* Foderé† has related a case which we deem quite conclusive in the affirmative; and the signs he has described will no doubt be generally met with under similar circumstances. They were the following:—extreme paleness of the whole body; no wound or external sign of violence; the umbilical cord flaccid; floating of the lungs with or without the heart; complete vacuity of the heart and great vessels, of the vena portarum, of the ductus venosus, and even of the capillary vessels. All the blood which could be collected did not weigh two ounces. The child lived long enough to be carried three leagues; hence death from this cause is not speedy, and the signs of respiration would be certainly found.

Röederer has remarked that the ligature may be applied to the cord after fatal hemorrhage for the purpose of deception, but the proofs of anæmia would elucidate the case. If three ounces of blood can be collected, it may be presumed that the child has not died of hemorrhage. In Foderé's case not two ounces could be collected.

We now pass to the consideration of the causes of death after delivery *by commission*; and it is commonly in this manner that infanticide is perpetrated in this country. They may be as various as those of homicide generally; but there are some which are more easily or more commonly employed than others. The following enumeration embraces the more usual and important varieties. Suffocation from division of the *frænum linguæ* and turning back of the tongue; stoppage of the aerial passages; asphyxia by strangulation or by deleterious gases, or by plunging into privies; torrefaction; drowning; wounds and bruises about the head or in different parts of the body; crushing of the head; punctures per rectum or in the region of the heart: to which may be added some of the causes mentioned under the criminal means of death during delivery. The criminal intention in many of these injuries would be self-evident. A recent case of infanticide in Guernsey was perpetrated by laceration of the *frænum linguæ* and puncture per rectum.‡ The proofs of murder were unquestionable.

The effects of injuries about the neck demand the strictest scrutiny; for strangulation is perhaps the most frequent of all causes of infanticide by commission. The fallacies by which it is beset are the "entortillement" of the umbilical cord; supposed injury from compression by the os uteri and vagina; or from the assistance which a woman might endeavour to render herself; possibility of post-mortem injury; and livor, or spontaneous suffocation.

The turning of the umbilical cord around the neck requires that the funis should be of

a certain length;* and the mark, if any remain, cannot be circular unless it have made a second turn. No abrasion or puckering of the skin ever takes place from this cause.† M. Klein,‡ who has made special observations on the subject, denies that any sugillation or even impression ever occurs from compression of the neck by the cord, by the os uteri, or vagina. He has seen many children who have died from the first of these causes; and in none did he observe any mark left about the neck. But in infanticide, as in homicide generally, criminal efforts to extinguish life are executed most frequently with characteristic violence, and accordingly injuries of the tracheal cartilages or of the deep-seated muscles of the vertebræ are sometimes found, or plain impressions of the fingers. A few years ago we had occasion to examine the body of a child which had been destroyed by strangulation with the fingers. The impressions were distinctly perceptible on each side of the trachea, and the mark of the fingers gradually increased in distinctness from the back of the neck forwards. The trachea was not injured, but on each side of it coagulated blood was found.

The assistance which a woman might have endeavoured to afford herself would be generally recognizable by the nature, situation, and direction of the marks. The case of Marguerite Granger, related by Foderé,§ affords an excellent, perhaps an extreme illustration of the kind of injury which might be expected in such a case; and his report shows that, though such injuries may be numerous, they will be superficial.

Chaussier|| asserts that injuries have been inflicted on the dead body for the purpose of determining an accusation against an individual. If such wounds or bruises have not been inflicted for twenty-four hours after death, there is no difficulty in deciding that they were not received during life. The lips of wounds are pale, without swelling or retraction. There is no clot of blood adhering to the surface, nor, in the case of contusion, is coagulated blood found in the surrounding cellular texture: hence there is no tumour. The characteristics of blows inflicted during life are tumour from extravasation of blood and serum; or clots of blood in the subjacent cellular tissue without tumour, or "incorporation of the blood with the whole thickness of the true skin, rendering it black instead of white, and increasing its firmness and resistance."

"In respect to external contusions," says Dr. Christison,¶ "experiments show that for some hours after death blows will cause appearances which in point of colour do not differ from the effects of blows inflicted recently before death; that the discolouration generally

arises like lividity, from an effusion of the thinnest possible layer of the fluid part of the blood on the outer surface of the true skin, but also from an effusion of thin blood into a perceptible stratum of the true skin itself; and that dark fluid blood may be even effused into the subcutaneous cellular tissue in the seat of the discolourations, so as to blacken or redden the membranous partitions of the adipose cells, but that this last effusion is never extensive."

"It is impossible," continues Dr. Christison, "to fix absolutely the limit of the interval beyond which contusions cannot be imitated by violence applied to the dead body. It appears to vary with the state of the blood, and the time which elapses before the body cools and the joints stiffen. Sometimes the appearance of contusions can hardly be produced two hours after death; sometimes they may be slightly caused three hours and a quarter after it; but I should be inclined to think this period very near the extreme limit."

The testimony of Chaussier* corresponds with what has just been stated. "If," says he, "the injuries have been inflicted soon after death, whilst the muscles preserve their contractility, there will neither be tumefaction, nor infiltration of blood into the cellular tissue, or the blood will only form a clot without adhesion to the divided surfaces."

Lividities or livor, which are the terms employed to express the nature of discolourations occurring spontaneously after death, may be easily distinguished from ecchymoses, which are the result of injury during life. Livor is generally found on the back and thighs, or on the parts of the body on which it has remained when becoming cold. Sometimes it extends more particularly to the head or neck or genital organs. Lividities assume varieties of appearance, but they are confined to the skin, and are greatest when the blood has long retained its fluidity. Infiltration or effusion of blood into the cellular tissue never occurs from them, nor are they ever attended by tumour.

Ecchymosis or sugillation, on the contrary, is characterized by a true effusion of blood, which has formed a coagulum, and this coagulum is intimately adherent to the meshes of the cellular tissue, and frequently forms a tumour. In the progress of putrefaction, indeed, the blood resumes its fluidity, escapes from the vessels, and collecting under the skin forms soft fluctuating tumours, which, on being opened, are found to contain a dark sero-sanguineous fluid. But it would be impossible for any person of moderate information to confound such appearances with the phenomena of true ecchymosis.

Death from torrefaction or burning is of rare occurrence in criminal cases, yet we are informed by Dr. Ryan† that an instance of this crime has been recently perpetrated in London. The circumstances to be investigated by the medical jurist would be, whether the child was

killed by burning, or the body was thrown into the fire after death from other causes. Some late experiments of Professor Christon* show that "a line of redness near the burn not removable by pressure, and likewise the formation of blisters filled with serum, are certain signs of a burn inflicted during life." The application of a cauterizing iron ten minutes after death did not cause redness, although vesications were produced; which vesications, however, did not contain serum, but were dry and filled with air.

Instances of infanticide by drowning are infrequent. The proofs would be found in the signs of extra-uterine life, the absence of other efficient causes of death, and the presence of phenomena which are usually observed in asphyxia from submersion. (See ASPHYXIA.) We may observe that the presence in the bronchi of a portion of the fluid in which the body was found is no proof of death by submersion; for fluids will pass into the bifurcations of the bronchi if the body have been thrown into water after death. If, however, any of the fluid, and particularly any foreign matters contained in it, were found in the stomach, death from submersion would be unquestionable, as it could only have arrived there from deglutition. The indications of struggling which are sometimes met with in adults destroyed by drowning, could not be expected in a newly-born child under such circumstances.

Death from criminal injuries of the head are distinguishable by the fracture of one or more bones in situations which, neither in the course of natural parturition nor in the case of sudden expulsion, are liable to them. Ecchymoses and wounds almost always accompany them.

In injuries of the head from violent compression criminally applied, it is highly improbable that the marks could be confounded with those which sometimes, though very unfrequently, occur during labour. The unusual situation, severity, and complication of the injuries, with the indications of extra-uterine life, would, in the absence of the signs of difficult labour, dissipate all doubt as to their origin. We shall here detail the marks of difficult labour which are usually met with.

In a first labour, even when there is no unusual disproportion between the head of the child and pelvis of the mother, and the delivery has been accomplished with moderate celerity, we observe in the presenting part of the child a tumefaction of uncertain extent and size. On dissecting this tumefied part, a serous infiltration, sometimes with sanguineous engorgement, is found under the subcutaneous cellular texture, and which does not exist in other parts of the head.

In a woman who has borne several children, whose pelvis is large, and the os uteri soft and yielding, this impression is so slight as to be scarcely perceptible, especially if the child is small, and the delivery have been quick. On the contrary, when the head of the child is large, the bones firm, and the labour slow and

painful, so that the head have been delayed in the pelvis, the tumour is large, prominent, and unyielding. When cut into, we not only find a sero-sanguineous effusion into the subcutaneous cellular tissue, but the pericranium is detached and elevated by a collection of dark fluid blood, the bone is brownish, and the connecting membranes are more or less elongated. These changes are still greater when the superior aperture of the pelvis is narrowed by an unusual projection of the promontory of the sacrum. Then the head is deformed, elongated in its greater diameter, flattened in the transversal. Sometimes even a depression or fracture, longitudinal, angular, or starred, of one or both parietal bones, may occur. All these phenomena are distinguishable from those produced by accidental or criminal violence by the nature and position of the tumour, and of the other injuries which result from the unnatural projections of the pelvis. Such deformity of the pelvis is ascertainable at any period after delivery; and where the usual proportions between the head of the child and pelvis of the mother exist, the appearances above adverted to are never met with.

We here terminate all the remarks we have to offer on the causes of the death of a newly-born child,* and venture to state that the indications afforded by them will be found applicable to the solution of the difficulties which can be reasonably anticipated on trials for infanticide. Undoubtedly instances may occur in which it will not be possible to demonstrate the cause of death, but such is the case also in other varieties of homicide. In infanticide the victim is incapable of resistance, and hence some of the ordinary proofs of homicide may be absent; but the kind and degree of injury necessary for the destruction of the life of a child are very rarely nicely measured by the perpetrator of the crime; and the violence committed is most frequently such as to leave no doubt as to the cause of death, and to constitute, at the same time, the most indubitable evidence of extra-uterine life. It is unquestionable, however, that medical evidence on trials for infanticide has not influenced the decisions of juries in the same degree as on trials for other kinds of murder. By some this has been attributed to the doubtful and hesitating manner in which medical witnesses have generally delivered their testimony;† by others to the impression that the killing of a new-born child, when perpetrated under the impulse of injured honour and the fear of disgrace, should not be classed with the other varieties of murder. The latter question we shall not attempt to discuss; but as regards the former explanation, we unhesitatingly express our conviction that the anatomical, physiological, and pathological phenomena on which medical evidence is founded on these occasions are as susceptible of positive conclusion as any other facts within the sphere of medical investigation. Never-

* For the signs of death by poisoning and deleterious gases, see TOXICOLOGY.

† Edin. Med. and Surg. Jour., vol. xxvi.

* Edin. Med. and Surg. Jour., No. cvii, p. 323.

theless, we are not surprised that medical men should frequently be unprepared to deliver their testimony with clearness and decision in criminal trials. The facts and information connected with these subjects are rarely applicable in the discharge of the ordinary duties of medical practice; and general practitioners in active occupation have, therefore, no great inducement, and seldom sufficient leisure to devote to the literary and experimental researches which investigations in medical jurisprudence demand, whilst it is to this class of practitioners that reference is generally made in medico-legal proceedings. The custom which prevails in Germany and other northern countries of Europe of appointing a medical officer for each district, whose especial duty it is to investigate all cases which become the subject of juridical proceeding, seems worthy of imitation in this kingdom. The establishment of such an office creates individual responsibility, and ensures a due preparation for the faithful discharge of it; and the concentrated experience thus acquired has contributed to the exactness and extension of medico-legal knowledge. Under existing arrangements in this country, the infrequency with which individual practitioners are called on to act, constitutes perhaps the chief reason why this department of professional study has hitherto been comparatively neglected.

III. We next proceed to inquire into the proofs whether the suspected mother has been recently delivered.

As collateral evidence, it is advisable to ascertain whether the general symptoms of pregnancy have pre-existed. It is evident that no conclusive opinion can be formed in such a case, auscultation and the *ballotement* supplying the only positive evidence of pregnancy. But if the menses have been suddenly suppressed, the mammæ and abdomen have enlarged, and no other symptoms of disease than inappetence, irritability of the stomach, and dyspepsia have followed, it may be reasonably presumed that the woman has been pregnant.

The proofs of recent delivery are furnished by an aggregate collection of signs, which, separately considered, do not admit of positive inference. In a woman recently delivered, particularly of a first child, the following appearances are very generally met with: the face is rather pale, the eyes are sunken and surrounded with a dark circle; the pulse is rather quick, full, and undulating; the skin soft, with some heat and moisture, having a peculiar acid odour. The breasts are tumefied, distended, and painful, yielding on pressure or suction a fluid having the characteristic properties of milk; the belly is soft, and the skin is wrinkled and marked with short red or white lines passing in different directions, chiefly towards the umbilicus; a separation of the linea alba is perceptible, particularly towards the umbilicus. The uterus is felt above the pubis. There is a discharge from the vagina either of a red, greenish, or light colour, and of peculiar odour. The genital organs are more or less tumefied, and considerably dilated in their whole extent; the

fourchette is lacerated; the os uteri is soft and relaxed, so as easily to admit of the introduction of the fingers, and a discharge similar to what has been just mentioned flows from it.

There is no known disease which will produce the concurrence of signs now enumerated, whilst after parturition, and particularly after a first labour, they almost uniformly occur.*

But the discovery of such a series of symptoms will depend altogether upon the period of time at which the examination was made. Zacchæus long since observed that the proofs of delivery were uncertain after the tenth day.† After the fourth or fifth they become less distinct, gradually diminishing, and at the end of a fortnight are indecisive. The possible fallacies are the sudden cessation of dropsies; the expulsion of hydatids or moles. The Foreign Quarterly Journal of Medicine and Surgery contains a case of the sudden disappearance of dropsy, in which the water was discharged per vaginam by passing down the fallopian tubes. In Rust's Magazin ‡ a case is related of the discharge of a "mole" preceded by the general symptoms of pregnancy, and accompanied by flooding and other signs of parturition. The discharge of the menstuous fluid after long retention might simulate some of the symptoms of recent delivery, but many of them, and those the most decisive, would be absent in all such cases; whereas, after delivery, and particularly of a first child, almost all would be found to concur.

IV. Do the phenomena presented by the supposed mother and child establish the suspected relationship?

The solution of this question is almost always easily determined in cases of infanticide by moral evidence; and indeed it is by moral evidence alone that it can be positively settled. Medical testimony must be confined to shewing that there is an agreement of the phenomena presented by the child with the indications of delivery observable in the woman. The data thus derived can be of a general nature only, and are confined chiefly to a comparison of the state of conservation or decomposition in which the body of the child was found, with the presumed period of delivery.

If the inquiry were not instituted for some days after delivery, it would be necessary to take into consideration the circumstances capable of accelerating or retarding decomposition. For instance, putrefaction proceeds most rapidly when the atmosphere is humid and still, and the heat ranges between 60° and 80° Fahr. It proceeds most rapidly in parts of the body

* A curious application of the knowledge of the signs of recent delivery has been mentioned by Capuron, *Médecine Légale*, p. iii. A young woman simulated pregnancy, and pretended to have been delivered, in order to obtain from her lover the execution of a promise of marriage. The latter claimed the child, which could not, of course, be produced. A charge of infanticide was brought against the pretended mother, who was compelled to show that she had not been delivered. This was attested by the medical examiners.

† *Quæstiones Med. Legales*, lib. 7, quæst. 2.

‡ Vol. 21.

which have sustained injury either before or after death.

It is important to remark that in bodies plunged into privies, putrefaction does not commence so soon as when they are exposed to the air; but having begun, it proceeds more rapidly in such a situation. Decomposition is retarded by submersion in water, so that two or three weeks generally elapse before, in bodies so circumstanced, putrefaction commences.

Some remarks on post-mortem examination, and on the drawing up of medico-legal reports with reference to the present subject, would furnish practical information of value, and hence form an useful appendix to this essay. It already, however, occupies the limits which can be assigned to it in the Cyclopædia, and we content ourselves with referring the reader to the Thesis of Lecieux, where the points now adverted to will be found admirably exemplified.

(Robert Arrowsmith.)

INFECTION, *infectio*, (not classical,) *infectus*, and *inficere*, Lat.—The meaning of this word has been, and perhaps still is, unsettled. It will be employed in this article to signify the deleterious or offensive qualities which certain matters designated by the terms malaria, matter of contagion, emanations, and effluvia, communicate to the air and other inert bodies; and likewise the pernicious effects which some of these substances produce on the human constitution. This description comprises, if we mistake not, all the physical senses in which the word is usually employed. It will be observed that, according to one of them, it is to a certain extent synonymous with contagion, and it is likewise made so by the custom of the majority of the profession; a custom which is in a great measure owing, we believe, to the word *contagion* being destitute of the verbal form, whence the phrases *to infect* or *to be infected* become convenient modes of expression. A good deal of confusion has resulted from an attempt to discriminate between contagion and infection, when the latter term is employed to express the transmission of disease from man to man; and in the article **CONTAGION** we have expressed an opinion that in this case the words should be regarded as strictly synonymous; but it will be observed that infection possesses a wider sense than contagion, being applied to cases of contamination which are never designated by the latter word.

Deleterious qualities may be communicated to certain bodies either by matters known only by their effects on the human constitution, or by those which affect perceptibly the sense of smell. Of the former an account will be found in the article **CONTAGION**, and in those on **MALARIA** and **MIASMA**. The latter consist of hydrogen and its compound gases, carbonic acid, azote, and perhaps other gaseous matters which are the result of animal and vegetable putrefaction aided by the presence of moisture. Their sources are various, such as cemeteries in which bodies are deposited at an insufficient

depth from the surface, or from which it has been found necessary to remove the accumulated remains; slaughter-houses; dissecting-rooms; neglected privies and drains; stagnant waters, in which organic recrements are undergoing decomposition, as is often exemplified in noisome swamps, or at low water on the banks of rivers near their mouths, when in the vicinity of populous towns; human beings accumulated into a small space with deficient ventilation, &c.

The two genera of infecting substances frequently co-operate in producing an effect on the human system. Thus it is commonly observed that contagious diseases are more generally diffused and assume a worse character in an atmosphere abounding in manifest impurities than in one which is free from them. During the prevalence of typhus at Paris in 1814, the mortality was observed by M. Jadioux to be frightful in those wards of the Salpêtrière which are situated near the sewer of the hospital; and it was very easy indeed to multiply examples of this description.

The bodies which are sensibly contaminated by infecting particles are various, and differ much in their power of receiving and retaining the contamination. Confined masses of atmospheric air receive it readily and retain it long, as likewise do solid bodies which possess the property of holding air in a quiescent state within their interstices, such as cotton, wool, cloths fabricated from these substances, fur, feathers, &c. On the contrary, smooth and polished surfaces are tainted with difficulty, and are readily cleared of the pollution. These facts are illustrated by the well-known experiment of Mead, who placed a portion of carded cotton near a morsel of putrefying meat under an inverted bell-glass, and thus ascertained that the downy substance became strongly impregnated with the odour and retained it long, whilst the contrary was the case with the smooth surface of the glass. The same rule is observable with respect to certain infecting particles of which our senses are unconscious, for the downy substances named retain contagious matter long, and hence become powerful fomites; but there is no reason to think that that species of marsh effluvia called malaria adheres to them so as to render them the media by which it is communicated to the human system.

Action of infecting substances on the animal economy.—We now come to the second branch of our subject, the consideration of the mode in which infecting agents operate on the human constitution, and the kind of change which they produce there.

If common odorous infecting matters are freely diluted with atmospheric air, we find that persons do not suffer from exposure to them, as is exemplified in the case of butchers, tanners, &c.; but in a more concentrated state they produce very deleterious effects, and occasionally instant asphyxia, which was illustrated by the well-known case of the exhumations in the cemetery of the Innocents at Paris, and is not unfrequently exemplified in attempts to

empty privies which have been long neglected. The slower but yet pernicious effect of the same cause is shewn in the unhealthy aspect of the inhabitants of filthy and ill-ventilated alleys in large cities of which the police is neglected. Those agents whose existence is recognized only by their influence on the animal economy are likewise found to be affected by admixture with pure air. The effect of dilution is very conspicuous in the case of human effluvia, which have their intensity much diminished in a free and pure atmosphere. Marshy emanations retain considerable noxious power at a distance from their source, but there is a point beyond which they are inoperative, shewing that diffusion in the atmosphere is ultimately destructive of their agency.

There are two hypotheses regarding the mode in which these matters act injuriously on the economy. According to one their operation is on the nerves of the part to which they are applied; the other supposes them to be absorbed from the same part into the circulation. In the present state of our knowledge it is impossible to decide in favour of one or the other of these modes, or to say that either of them is that which is uniformly operative. The very rapid action of certain mephitic gases leads to the supposition that an impression on the nerves of the air-passages is sufficient for the production of *their* poisonous effect on the system. The cutaneous surface, the mucous membrane of the air-passages, and the corresponding surface of the alimentary canal, have each of them been supposed by different medical reasoners to be the channel by which noxious agents find access to our system. Lancisi, who first reasoned with any degree of accuracy on this subject, conceived that such agents might be transmitted by all these media to the interior; and we believe that he was correct in supposing that any of them might be the channel through which the system was contaminated. When the epidermis is entire, the absorbing power of the cutaneous surface is so very feeble, and its nerves are so protected by an inert covering, that it is probable that gaseous matters of a noxious nature rarely act in this way; but more concentrated substances often do so when the surface is broken, as in inoculation or injuries from dissection, which last certainly produce a species of infection. The first impression from infecting matter diffused in the atmosphere was supposed by the late Dr. Jackson to be made on the alimentary canal; and it is very probable, at least, that by the act of deglutition, which persons are almost incessantly performing to swallow their saliva, noxious particles may be conveyed thither; and whether we regard its mucous membrane as an absorbing or sentient surface, it is one through which such particles are very likely to act on the animal economy. But the most ready access for atmospheric poisons to the system is afforded by the air-passages. The experiments of Nysten and Edwards have proved that hydrogen, azote, and other gases, are rapidly absorbed by the lungs; and analogy would lead us to attribute a similar suscepti-

bility of absorption to contagious and other miasmata; whilst, if we reject the necessity of absorption, and assume that a nervous impression is all that is required, we find a widely extended and sensible membrane on which the deleterious corpuscles may operate.

The local operation of these poisons has been considered as far as our present knowledge of the subject admits. It remains that we should notice their more general effect, or their operation on the animal economy, if we are to take such a view, after they are absorbed into the circulating mass. To discuss the various changes which odorous infecting matters effect in the system—the modes in which they destroy life or impair its vigour, would lead to a very lengthened disquisition, and one which perhaps belongs rather to the physiologist than the practical physician. But the agency of the morbid poisons by which what is strictly called infection of the human constitution is produced, and diseases are engendered ranking among the most important of our nosologies, demands some notice in this place. To whatever parts of the body morbid animal poisons or marshy effluvia may be in the first instance applied, and however various the diseases ultimately engendered by them, we believe that their primary constitutional effect is on the nervous system. The period which generally intervenes between the application of a contagious or paludal poison and the full development of the disease engendered by it, is not one of health; and the slight signs of indisposition which exist are referable to the nervous system solely, excepting in a proportion of the cases arising from marsh effluvia, where some disorder of the bowels is after a time associated with the indications of nervous affection. These indications are extreme debility, inertness in motion, irritability and despondency of mind, incapacity of continued attention, noises in the ears, occasional giddiness, inappetency or morbid appetite, and extreme susceptibility of the impression of cold, the vascular system being during this period free from manifest disturbance. The first symptoms of the invasion of the actual disease partake of the same nervous character. They are giddiness of the head, pain there and along the spine, marks of irregular distribution of heat, rigors, inappetency, nausea, and in a proportion of the cases of some diseases, the exanthemata for instance, convulsions. One morbid poison, that of hydrophobia, appears to confine its whole operation to the nervous tissue, an extraordinarily erethismal state of this tissue giving rise to all the phenomena of the disease, and at its fatal close there being no traces of local affection of uniform occurrence or of such importance as to be considered as the source of the symptoms witnessed during life. In most diseases the vascular and other systems are ultimately involved, but accurate observation will always discover preceding indications of an affection of the sentient portion of the frame.

For the mode of purifying infected substances see DISINFECTION.

(Joseph Brown.)

INFLAMMATION, from *inflammo*, to burn; hence, also, phlogosis, phlegmasia, phlegmon, &c. from *φλέγω*: a name given on account of the resemblance of spontaneous inflammation to the effects of the application of fire to the living body.

There has hitherto existed so much diversity of opinion respecting the proximate cause or nature of inflammation, and it is a disease assuming such an infinite variety of forms, that it is scarcely possible to give a strictly correct and scientific definition of it. The following, proposed by Peter Frank, is the most comprehensive and accurate which has hitherto appeared:—"Calor partis, tensio, moles, ac durities acuta; ut plurimum cum sensu doloris fixi, nunc ardentis, nunc pungentis, pulsantis, nunc gravati, aliquando nullæ, cum colore vivido, nunc profundius rubro; sæpissime cum febre, pulsu frequenter pleno, forti ac duro, sæpe contracto ac parvo, aliquando naturali; ac tumoris evidenti, aut in suppurationem, aut in gangrenam nisu, dicitur inflammatio." P. Frank, however, judiciously adds that the presence of all these signs is not necessary to constitute inflammation, and that frequently some of them are wanting.

So large a proportion of the diseases which affect the human frame are of an inflammatory nature, that the study of the pathology and treatment of inflammation has at all times been considered a subject of interest and importance. The opinions entertained by professional men at different periods on this branch of medical science have necessarily varied with the prevalent theories of the day. The writings of the older authors abound with speculations, more or less ingenious, respecting the nature, causes, and treatment of inflammatory affections; and although they do not supply much information founded on the sober and rigid deductions of experimental philosophy, a brief review of the theories of inflammation may prove both interesting and useful, as an occasional ray of light sometimes glimmers forth in the midst of much obscurity, and the errors into which those who have indulged in visionary conjectures have fallen, may serve as beacons to protect us from a similar danger.

The general principles respecting the nature of diseases, promulgated by Hippocrates, exercised a considerable sway over medical science for above two thousand years, holding a more or less prominent station in the systems of almost every sect down to the close of the last century. These views laid the foundation of the Humoral Pathology, in which the first material innovation, and especially in the theory of inflammation, was made by Paracelsus in the fifteenth century, who, having bestowed considerable attention on the study of chemistry, endeavoured to account for all diseases by changes in the chemical composition of the animal fluids. This gave origin to the sect of *chemical physicians*, who violently opposed the doctrines of the school of Hippocrates and Galen. There was a strong tendency in the physiologists of that period to ascribe exclusively the phenomena of life to the influence of the same

laws as those which regulate the motions of inanimate matter; and some, conceiving they could satisfactorily explain all the operations of the animal economy on the principles of mechanics, founded a sect of *mechanical physicians*.

The ignorance which had hitherto prevailed respecting the circulation of the blood contributed no doubt very materially to prevent the introduction of more correct views of pathology: it was very generally believed that the liver was the centre of the vascular system, from which the blood went forth by day to the extremities, returning again by night; if any peccant matter irritated the liver, the blood was sent out more forcibly; and if, at the same time, any part of the body were either weakened or irritated, a swelling was produced by the flow of humours to this place: fluxions might therefore happen either from weakness or irritation; the peculiar nature of the swelling was supposed to be modified also by the nature of the humour: blood produced the true phlegmon, bile being the supposed cause of erysipelas, &c. The blood and humours were imagined sometimes to stagnate in a part from want of expulsive power, and this was termed congestion; whilst fluxion or defluxion denoted a sudden flow of humours from a distant part.

The discovery of the circulation of the blood by Harvey in the beginning of the sixteenth century, was not followed by such an immediate improvement in the theory of inflammation or of other diseases as might perhaps have been expected. Although the course of the blood in the large vessels, and the connection between the lymphatic and sanguiferous systems through the medium of the receptaculum chyli and thoracic duct, were facts clearly ascertained, the functions of the capillary circulation and of the nervous system, which are more immediately connected with the proximate causes of inflammatory affections, were yet very little understood.

Böerhaave, one of Stahl's contemporaries, a professed eclectic, endeavoured to select whatever appeared most valuable in all preceding systems, and to combine the whole into a uniform body of medical science. He took the humoral pathology as the basis of his theory of disease, and especially of inflammation, but adopted also many of the opinions of the chemical and mechanical sects. He considered that the blood and humours were vitiated in disease either by an excess of acid or of alkali, or by becoming too viscid and glutinous, or too thin and watery; that the circulation of the fluids might be too rapid or too slow; that the fibres of the solids were either too feeble and relaxed, or too rigid and elastic; that there were also separate diseases of the large vessels and of the capillary system.

The following summary will afford a connected view of the fanciful speculations of the different sects whose opinions we have thus briefly noticed. The propelling force of the heart having been ascertained, and microscopic observations having been made on the capillary

vessels, and on the size of the globules which pass through them, the mechanical physicians imagined they could satisfactorily explain many of the phenomena of disease by the effects of friction, pressure, and trituration, and by the relative dimensions of the vessels and of the globules which they circulate: these globules were described by Leeuwenhoek as conical; so that, when forced into very small vessels, they became fixed like a wedge. The combinations and decompositions of the chemists added to the preceding theory that of the acrid and inflamed, the inspissated, fermented, or putrid state of the humours. They were thus heated by the excess of friction, of motion, or of pressure, or rendered acrid, irritating, and inflammatory by an excess of acid; they distended the vessels by their rarefaction, were condensed by evaporation, becoming then corrupt and dissolved; or when too viscid and inspissated, they stagnated in the vessels, which were too feeble to expel them, and became cold and concrete, until some strong reaction took place by which the crude morbid humour was concocted, and the tumefaction resolved either by the formation of pus or the elimination of the concocted humour through some of the excretory organs. At other times, the solids being too lax and weak for the perfect elaboration of the fluids of nutrition, became corrupted and dissolved, acquired an excess of alkali, and gave origin to putrid diseases. Their treatment was adapted to these views of the nature and causes of diseases, and we consequently find in their therapeutics refrigerant remedies, delayants, inspissants, antiseptics, solvents, depuratives: and some slight share of influence in the production of disease being allowed to the solids, there were also remedies intended to increase the tone and cohesion of the fibres; others to relax and lessen rigidity, and others to allay excessive sensibility.*

The contending sects of chemical and mechanical pathologists were completely overthrown in the beginning of the seventeenth century by the opinions of the celebrated Stahl. Having noticed that the changes which the components of the body undergo during life, differ greatly from those that take place after death, he conceived, like Hippocrates, that there must necessarily exist some additional principle during life by which the action of the mere physical laws is counteracted and modified, and from which the body thus derives its distinctive character of vitality. He imagined this agent, which he called *anima*, to be something distinct from the body, possessing a species of intelligence which enabled it to act the part of a rational being, and to superintend all the operations of the animal economy. There is an apparent analogy between the *anima* of Stahl, and the *ψῆσις* of Hippocrates: the latter, however, only proposes his term as a rational manner of explaining the facts he observed, whilst the former considers his principle as an

abstract metaphysical spirit, capable of acting independently of the state of the body, and without any physical necessity arising from that state. In other respects Stahl adopted most of the opinions of Hippocrates, and engrafting on them some of the doctrines of the chemical school, his pathology turned chiefly upon the opposite states of plethora and cacochymy.

Van Helmont, one of the most distinguished of the Vitalists, proposed a more rational theory of inflammation than any of his predecessors. According to him there were two circumstances indispensable to the development of inflammation—the action of a stimulus on parts endowed with sensibility, and an increased activity of the arterial system, followed by redness, pain, heat, and swelling in the part thus stimulated. He not inaptly compared the action of the stimulus to that of a thorn thrust into living flesh: this excited the alarm of his *archæus*, who immediately caused an increased flow of blood to the part, and set up a defensive and reparatory process. He adopted also many of the chemical opinions, conceiving his ideal inflammatory thorn to be generally acid, &c.

The humoral pathology, after keeping for a long period almost exclusive possession of the medical schools, began to receive a serious check from the doctrines taught at the University of Halle by Hoffmann; who contended strongly against the long-established notion that a vitiated state of the fluids was the primary cause of the great majority of diseases, and maintained that it was much more rational to attribute their various phenomena to morbid conditions of the solids, by which the fluids themselves were contained, elaborated, and kept in constant motion. There were, according to him, two principal morbid states of the solids, *spasm* and *atony*; and as the motions of the solids seemed to depend in a great measure on the influence of the nerves, he ultimately referred most diseases to affections of the nervous system: he attributed to the nervous principle the functions which Stahl ascribed to his *anima*, and Hippocrates to his *ψῆσις*. These views of disease were zealously embraced by Baglivi in Italy, Barthez at Montpellier, and Cullen in our own country: the latter applying them with great talent and ingenuity, as will be seen presently, to the theory of inflammation. The humoral pathology soon became completely exploded, and a totally opposite system was substituted in its place, called that of the *Solidists*. The introduction of this system was greatly favoured by the labours of the celebrated Haller, whose important discoveries in anatomy and physiology have contributed so much to our knowledge of the intimate structure and functions of the different organs, and particularly of the nervous system.

Dr. John Brown of Edinburgh, adopting some of the opinions of the Solidists, founded on them a most fanciful system of physiology and pathology, which, although less noticed in this country, was eagerly adopted in France and Italy, and partially also in Germany, and had a most baneful effect over the practice of medicine in these countries. According to Dr. Brown,

* For a full account of all the leading medical theories, see Broussais' *Histoire des Doctrines Médicales*.

life is only sustained by the action of either external or internal stimuli on the body through the medium of the nervous system : this susceptibility of impression he calls *excitability*. If the action of stimulants be too much increased, this gives rise to diseases with excess of action (*sthenic*), and, when deficient, to diseases of debility (*asthenic*.) Asthenia is subdivided into *indirect*, when the excitability is exhausted by excessive excitement, and into *direct* when the deficiency of excitability arises from a want of adequate stimulus. Dr. Brown attended more to the state of the general excitability than to the condition of the organs ; there were thus two deviations of the excitability from the standard of health, constituting the *sthenic* and *asthenic* diatheses, and only two great classes of diseases : he maintained, moreover, that both sthenia and asthenia could never exist together in the same individual ; so that, if an individual presenting signs of general debility was seized with pneumonia or hepatitis, the local affection, however severe, was attributed to debility, and treated by stimulants : inflammations were thus divided into two classes, the *sthenic* and *asthenic* ; and idiopathic fevers, hemorrhages, congestions, convulsions, plethora, &c. were classed among the diseases of debility. He asserted that the diseases of direct and indirect debility so greatly preponderate over those of the opposite class, that out of every hundred cases there were scarcely three of genuine inflammation : there were accordingly only two classes of remedies, and these pernicious principles necessarily led to a most incendiary system of practice. The apparent simplicity and plausibility of this theory unfortunately obtained for it numerous adherents.

The Italians, after adopting Brown's theory, discovered at last its fundamental errors, and engrafted on some of his physiological principles a new system called the *contro-stimulant* : they admit two opposite diatheses, one of *stimulus* and one of *counter-stimulus*, and have founded a third class of diseases consisting of local irritations, which may give rise to either of the two preceding morbid states of the constitution : they accordingly adopt only two classes of remedies, the stimulants and counter-stimulants ; the latter being supposed to remove directly, and without even any evacuation, the excess of stimulus in the system, whilst stimulants act in a manner directly the reverse : the animal fibre, it is also supposed, will tolerate the action of stimulants or counter-stimulants exactly in proportion to the strength of the existing diathesis, either of stimulus or counter-stimulus. Venesection is, however, considered as an active counter-stimulant. Counter-stimulant remedies include above nine-tenths of the *Materia Medica* ; we have thus tartar-emetic, bark, mercurial and saline purgatives, preparations of iron, all kinds of bitters, &c. classed together as suited to combat inflammation. The really stimulating remedies are limited to a very small number, such as opium, fermented liquors, &c.

Several distinguished physicians introduced about this period the more practical and judicious method of investigating carefully the

symptoms, course, varieties, and post-mortem appearances of diseases. A number of highly valuable monographs of disease were the result of this course of proceeding. Among these we must first mention, as particularly deserving of notice, the works of the great Sydenham. He was the foremost to perceive the necessity of descending from the engaging but profitless regions of fanciful speculation, to the more laborious task of a rigid and accurate observation of the phenomena of nature ; and his example had a powerful influence in giving a new and better direction to the investigations of medical science throughout Europe. Many excellent descriptions of the inflammatory affections of separate organs, and of the alterations of structure which they induce, are also to be found dispersed throughout the writings of Grant, Stoll, De Haen, Morgagni, Bonetus, Wagler, Røederer, &c. Bordeu, in his work on chronic diseases, gives a very minute and faithful account of the irritative and inflammatory affections of the digestive tube, and lays considerable stress on the sympathetic influence exercised by the abdominal viscera over every other part of the animal economy.

Inflammatory diseases had not, however, hitherto formed the subject of any special and separate inquiry ; and the merit of having contributed the first scientific work on this important class of diseases belongs to our talented countryman Dr. Carmichael Smith, who in 1788 published an admirable paper on this subject,* in which he took a comprehensive view of the peculiarities of inflammation as they are observed in the principal elementary tissues that enter into the composition of the body : this was laying the foundation of the morbid anatomy of tissues, from the cultivation of which medical science has since derived such incalculable advantage.

The next separate treatise on inflammatory diseases was one on chronic inflammations by M. Pujol, of Castres in Languedoc, which obtained a premium from the Royal Academy of Medicine of Paris in 1791 : in this valuable work the author first considers the chronic inflammatory affections of the surface of the body, and next those in succession of the three splanchnic cavities.

The preceding writers had confined themselves to a general description of the different varieties presented by inflammatory diseases, and of the changes of structure they induce. The celebrated John Hunter instituted an experimental inquiry into the essential nature and proximate cause of the process of inflammation, an undertaking for which he was particularly well qualified by his admirable knowledge of the minute anatomy of tissues ; and his great work on the *blood, inflammation, and gun-shot wounds*, appeared in 1794 : this was the first experimental and scientific treatise on the theory of inflammation ever published ;†

* Medical Commentaries, vol. ii.

† A small treatise was published at Florence by Dr. Vacca in 1765, entitled *Liber Inflammationis morbosæ quæ in humano corpore fit, natura, causis,*

it is distinguished for depth and accuracy of observation, acuteness of reasoning, and original and enlarged views of the laws which regulate the functions of life, and must ever be considered as a lasting monument of the author's genius. We shall frequently have occasion to refer to it in the course of this article.

The modifications occasioned in disease by the structure of the part affected, were beginning to excite more general attention, as appears by the writings of Dr. William Hunter, John Hunter, the two Monros, and Dr. Cullen, as well as by the splendid collections of pathological preparations made by the four former. M. Pinel, sensible of the many advantages that might be derived from a more comprehensive study of the influence of texture in modifying disease, made this the ground-work of his valuable *Nosographie Philosophique*, which was first published in 1797. Although some imperfections must necessarily attach to every nosological arrangement in the present state of medical science, the plan followed by this distinguished pathologist was infinitely superior to that of any of his predecessors, and had a highly favourable influence on the medical opinions of the time. The phlegmasiæ constitute the second class of the *Nosographie Philosophique*, and are divided into five orders, founded on the five principal animal tissues—inflammations of the cutaneous tissue; of mucous membranes; of serous membranes; of the cellular tissue and parenchymatous texture of organs; of the muscular, fibrous, and synovial tissues: this is exactly the division that had been adopted several years before by Dr. Carmichael Smith.

It was the *Nosographie Philosophique* that suggested to Bichat the plan of his great work on the anatomy of tissues. This justly celebrated work may be considered as having laid the foundation of the improvements made in France in every department of anatomical and physiological science, since the beginning of the present century: it is only necessary to refer in proof of this to the labours of Laennec, Bayle, Majendie, Broussais, Andral, Louis, Lallemand, Rostan, &c.; and as relating more exclusively to the subject of the present paper, to the *Histoire Anatomique des Inflammations* of M. Gendrin, by far the most comprehensive and practical work that has yet appeared on inflammation; and to another valuable work, entitled *Recherches Experimentales sur l'Inflammation*, by M. G. Kaltenbrunner, published in the *Répertoire Général d'Anatomie et de Physiologie Pathologique*.

The cultivation of physiology and pathology has, during the same period, been pursued with great success in our own country. Among the many contributions to general or special pathology, may be mentioned those of Baillie, Thomson, Hunter, Philip, Hastings, M. Hall, Abernethy, Astley Cooper, Lawrence, Travers, Parry, Cheyne, Bright, James, Elliotson, &c.

effectibus, et curatione; but although containing some excellent observations, the work was chiefly speculative.

Before concluding this brief historical sketch, we must notice the views respecting febrile and inflammatory diseases promulgated a few years since by Broussais, and very generally adopted in France. Although carried beyond their just and reasonable limits, Broussais' opinions have been the means of introducing a highly beneficial change in the system of practice of that country, by exploding Dr. Brown's phlogistic method of treating diseases which was previously in almost general use.

Whilst Brown committed the great error of referring most diseases to a morbid state of the general excitability, overlooking in a great measure the constitutional effects of local diseases, Broussais, influenced probably by his more extensive acquaintance with pathological anatomy, founded his system of *Physiological Medicine* on the principle that all diseases affecting the general health have a local origin. Instead, also, of considering a morbid condition of the nervous system to be the proximate cause of all diseases, and the great majority of them as the effect of debility, he maintains that they depend much more generally on affections of the vascular system; that they originate in various degrees of irritation, congestion, and inflammation in some one organ, disturbing by morbid sympathy the functions of all the others; and that the great majority of diseases are, in fact, of an inflammatory nature. Local irritations and morbid sympathies constitute thus the fundamental principles of Broussais' system; many debilitating agents, he conceives, excite inflammation, and the deficient action of one organ may excite a sympathetic irritation in others. To the affections of the mucous membrane of the alimentary canal he attributes an inordinate degree of importance, more particularly the sympathy of the digestive with the other vital organs. He asserts that fever is always the effect of an irritation of the heart, either primitive or sympathetic: that every form both of continued and intermittent fever has for its primary cause inflammation of the mucous membrane of the stomach and bowels, which he terms *gastro-enterite*; he completely repudiates the notion of there being any such diseases as idiopathic or essential fevers, maintaining that they are all to be explained exactly on the same principles as the symptomatic fever of pneumonia: all the exanthemata, hepatitis, pyrosis, and a vast number of other diseases, are, according to him, complicated with gastro-enterite; and we heard him even boldly assert in his lectures, that hydrophobia was only a gastro-enterite, frequently complicated with some degree of inflammation in the pharynx and brain!—a most remarkable instance of the dangerous extent to which the distortion of facts may be carried by an immoderate love of theory. An exposition of the fallacy of Broussais' opinions respecting fever will be found in the introduction to the article FEVER.

In writing upon a branch of pathology which has been the subject of so much investigation as inflammation, we cannot avoid re-

peating a great deal that has often been previously stated by others: as a reference to authorities on all points respecting which there can be no difference of opinion would be endless and inconvenient, we think it preferable to state here generally, that the sources from which we have chiefly derived assistance in the composition of this article, are the works of John Hunter, Thomson, Travers, Craigie, Elliotson, Andral, Gendrin, and Kaltenbrunner. Whenever we have occasion to mention opinions which possess any degree of novelty or originality, we shall either quote the author or refer to his work.

Physiological and pathological considerations on the circulation.—There are three of the elementary parts of the body that appear to be primarily and more essentially affected in inflammation: these are the bloodvessels, the nerves, and the blood. As every rational theory of disease must be founded on a correct view of the healthy phenomena of life, we shall offer a few observations on the action of each of these parts in the living body, before proceeding to the details of the theory of inflammation.

The minute ramifications of the arteries and veins, and the capillary system of vessels, being the principal seat of the morbid phenomena of inflammation, it is important, therefore, to attend to the peculiarities of the circulation in these vessels. It is now generally admitted that the arterial branches acquire a greater power of contractility in proportion as they become smaller, and that the arterial trunks are less contractile and more elastic. That the minute ramifications of arteries are endowed with a high degree of contractility, in virtue of which they are enabled to carry on the circulation independent of the action of the heart, is proved by a variety of circumstances. It is by this order of vessels that the functions of nutrition and secretion are performed, and it is absolutely necessary for the uniform and uninterrupted accomplishment of these varied and highly important functions, that they should have the power of controlling the motions of the fluid circulating within them. The relative momentum of the blood in different parts of the body, or the quantity of the blood and its velocity, are perpetually varying from the influence of external stimuli or internal causes; and this variable state of the momentum of different portions of the arterial system is a decisive proof of the vital contractility of its vessels. We thus observe the minute vessels of the cheek, in the act of blushing, acquiring increased activity and admitting more blood; while under the influence of depressing passions, such as fear, they are suddenly emptied, and the countenance becomes pale. Local inflammation is stated by all pathological writers to be characterized by a rapid throbbing pulsation of the vessels in the part affected, while the action of the heart and arteries of other parts of the body is not increased. If a person having inflammation in one hand be bled in both arms at the same time, twice or thrice as much blood will flow from the

diseased side as from the other. It is partly by the contractility of the extreme vessels in animals which have no heart, that the fluids in the lymphatics and lacteals are absorbed and moved. The minute arteries, like muscular tissues, retain the power of contracting after breathing has ceased; this is the cause of the empty state of the arterial system after death, for the small arteries and capillaries continuing to contract, empty their blood into the veins, while they receive no fresh blood from the heart. When death is rapidly occasioned by lightning or any violent narcotic poison, the action of the arterial and whole muscular system being suddenly destroyed, the arteries are found filled with blood as well as the veins.

The preceding facts respecting the active and independent power of the small arteries and capillaries over the circulation of the blood, have been strongly confirmed by the interesting microscopic observations of Dr. Thomson, Dr. Wilson Philip, and Dr. Hastings, for an account of which we must refer the reader to the writings of these distinguished physiologists.

It is, in the mean time, evidently impossible not to admit that the action of the heart and large arterial trunks, or *vis a tergo*, must assist in carrying on the capillary circulation. A constant supply of fresh blood is transmitted by each contraction of the heart, which must have the effect of distending and stimulating the action of the smaller vessels. When the contractions of the heart are unusually violent and rapid, the blood will no doubt be propelled through the small vessels, and especially through those within its vicinity, with a degree of force that will completely overcome the contractility of these vessels, and give them the appearance of passive canals; but this circumstance does not appear to us by any means sufficient to prove that under a quiet state of the circulation, and especially in parts of the body remote from the heart, the extreme vessels and capillaries have no controul over the course of the blood: the reverse of this has, in our opinion, been satisfactorily established by the facts and experiments already adduced. We conceive, therefore, that it is more reasonable to admit the influence of both causes in the circulation of the extreme vessels, and that the advocates on each side of the question have been much too exclusive.

The preceding are highly important facts, which will require to be taken into consideration in investigating the nature of inflammation. It should also be stated, that according to the latest experiments, it would appear that the arteries do not terminate in exhalents, but that both exhalation and absorption take place through the pores of the thin coats of the vessels.*

While we consider the independent vitality of the minute arteries as the most efficient agent by which they carry on the circulation, it is but reasonable to admit that the laws of

* Majendie's Physiology, p. 353, 479, (Dr. Milligan's translation.)

capillary attraction may afford some degree of assistance; for the living body is never completely exempt from the influence of physical laws. Dr. Marshall Hall has lately made some interesting microscopic observations on the action of the capillary vessels. He describes them as a network of pellucid vessels, differing from the small arteries in the circumstance that they subdivide without becoming smaller, and freely anastomise with each other, like nervous plexuses, forming thus an intermediate system of vessels between the arterial and venous systems. He states several reasons for inclining to the opinion that they are rather passive than active canals, through which the blood is circulated by the impulse of the arteries, the absorbing action of the veins, and also by capillary attraction. The facts brought forward in support of this opinion do not, however, appear to us sufficiently conclusive to controvert the numerous proofs we have already mentioned in support of the opposite opinion, and we consider it, therefore, a subject requiring further investigation. Dr. Marshall Hall fully admits the contractility of the small arteries.*

Dr. Reuss of Moscow published, some years ago, an account of experiments tending to shew that galvanism exercises a locomotive effect on the circulating fluids. This singular property has been more fully investigated of late by M. Dutrochet,† who has made some very interesting discoveries respecting the circulation of fluids, and has applied them with considerable ingenuity to the functions of vegetable life. M. Dutrochet has ascertained that when two fluids of different densities are only separated by a thin bladder, they exercise a double power of attraction over each other, which leads to the formation of two currents passing through the bladder in opposite directions and of different strength: the necessary result is a greater accumulation of fluid on one side of the bladder, in the direction of the strongest current, and a diminution of fluid on the other side. He conceives this property to depend on differences of density, of chemical composition, and of states of electricity. He has demonstrated the existence of a double current of this description through the vesicular texture of vegetables, and he calls the introduction of fluids into the vesicles *endosmosis*, and their expulsion *exosmosis*. He endeavours to account in this way for the ascent and descent of the sap, and for the circumstance of the roots of plants taking always a direction downwards, and the stems a direction upwards. This property is shewn to differ from capillary attraction. May not *endosmosis* and *exosmosis* be reasonably supposed to have some influence over the circulation in the extreme vessels in animals as well as in vegetables? This has already been made the subject of some highly interesting experiments by Mr. Faust‡ and Dr.

Mitchell* in America, and Dr. Stevens† in our own country. These gentlemen have clearly proved that gases are subject to the singular laws of *endosmosis* and *exosmosis* as well as fluids, and they have deduced from the facts they have observed a completely new and very ingenious theory of the function of respiration.

The connection and mutual influence of the two great systems, the vascular and nervous, on which mainly depend the functions of life in the higher classes of animals, has often been an interesting subject of inquiry with physiologists, and is one that involves considerations of the highest importance also to the pathologist. It may be necessary to premise that there are two great divisions of the nervous system, the first including the cerebro-spinal organs and their nerves, and the second the ganglionic system of the great sympathetic; and that the vascular system may be also divided into two sections—the circulation of the heart and large vessels, and that of the smaller and extreme vessels.

The heart and larger vessels receive but few nerves directly from the cerebro-spinal portion of the nervous system, their nerves being principally supplied by the ganglionic system of the great sympathetic, which appears to have the organic or nutritive functions of life more especially under its influence. The two divisions of the nervous system are, however, intimately connected by the numerous branches the great sympathetic receives from the spinal marrow, and by a few smaller branches coming from the brain.

There has been much difference of opinion among physiologists respecting the degree of influence exercised by the brain and spinal marrow over the organs of circulation; some concluding from their experiments that the action of the heart and bloodvessels is wholly independent of this portion of the nervous system; while others adopt, as the result also of experiments, a directly opposite opinion. The medium between these contradictory views approaches probably the nearest to truth; and the following facts may, we think, be considered as satisfactorily established by the joint testimony of experiment and pathological observation.‡ The action of the heart and large vessels is not immediately dependent on the influence of the cerebro-spinal nerves, for these organs continue to carry on the circulation after the brain and spinal marrow have been completely destroyed; they preserve, however, this independent power only for a short time, as their contractions

mose and Exosmose of Gases, and the Relation of these Phenomena with the Function of Respiration. —American Journal of Medical Sciences, vol. vii. Philad. Nov. 1830.

gradually become weaker, and completely stop at the end of a few hours. It is evident, therefore, that the functions of these organs, although partially removed from the direct influence of the brain and spinal marrow, cannot be continued in full vigour and activity after the destruction of this important portion of the nervous system. We see, likewise, these positions clearly illustrated by the natural phenomena both of health and disease. The action of the heart is not perceptibly affected by the ordinary operations of the mind, while it is frequently either quickened, depressed, or totally suspended, on the occurrence of sudden and powerful emotions; the functions of the heart are also not disturbed by partial diseases of the brain or spinal marrow, but very extensive lesions of these organs lead inevitably to some alteration in the state of the circulation.

The circulation in the extreme vessels (arteries, capillaries, and veins) is also in a great measure independent of the direct influence of the cerebro-spinal portion of the nervous system, for when the communication of a part of the body with the brain and spinal marrow has been destroyed, as, for instance, in paralysis, the function of nutrition is still carried on, although with diminished activity. The blood-vessels are chiefly supplied with nerves from the great sympathetic; the nervous filaments follow the ramifications of the arteries, subdividing most minutely around them, forming plexuses and penetrating their coats; the nerves of the cerebro-spinal system are also largely distributed, along with the bloodvessels, throughout the texture of many organs, conveying additional stimulus, although, as just stated, not absolutely indispensable to the action of the vessels. It may therefore be truly said, that wherever there are bloodvessels there are also nerves, and that there is scarcely a particle of organized animal matter without nervous tissue.

It is not, therefore, surprising that the varied and important functions of the extreme vessels should be under the immediate and powerful influence of the nervous system, and more especially of the ganglionic nerves of the great sympathetic. This is rendered obvious by innumerable facts both in physiology and pathology. The activity of the circulation in these vessels, and the various changes which the circulating fluid undergoes in the process of nutrition, secretion, &c., are, it is well known, accelerated, retarded, or otherwise altered, according to various modifications of sensibility. A striking proof of the important offices performed by the nervous system in these functions is also afforded by the result of Dr. Wilson Philip's experiments on the influence of galvanism over the function of secretion.*

Some physiologists have conceived that the nervous system has even a direct influence on the blood in the extreme vessels, an opinion which Andral is inclined to favour, as will be seen by the following extract from his patho-

logical anatomy:—"Barthez has said a great deal about a direct influence exercised by the nervous system over the blood: I grant that such an idea seems unfounded if we consider the blood only as it is in its great vessels; but in the capillaries, where it comes in contact with the solids and is confounded with them, where it manifests signs of vitality, and where in conjunction with the nerves it gives life to the organs it traverses;—in these, I say, who will venture to deny the influence of the nerves over it? In the capillaries is exerted in full force that law of mutual dependence that connects all the parts of the system, and makes of so many different elements but a single whole, of so many partial lives a single life. In them the nerves must act on the blood, as the blood acts on the nerves."^{*}

It should be remembered, on the other hand, that the nervous system is immediately dependent on the stimulus of blood for the preservation of its power, for this is completely destroyed the moment the nervous centres are deprived of arterial blood: there is, therefore, no fact in physiology better established than that of the intimate connection and mutual influence on each other of the vascular and nervous systems. They are the two that are first developed in the embryo, and they fulfil the most important offices in all the phenomena of life. These considerations are of considerable importance to the investigation of disease, as it will be seen that the various morbid conditions of the sensibility constitute one of the essential features of the process of inflammation.

We have next to consider the properties and uses of the blood. The ancients were so little acquainted with the structure and formation of the body, that perceiving the secretions and excretions generally vitiated in disease, they naturally considered the morbid conditions of the blood and other animal fluids as the primary and exclusive source of all diseases. After the humoral pathology had prevailed for many centuries, the rapid progress made in the science of anatomy and physiology about the time of Haller led pathologists into the opposite extreme of referring exclusively all the phenomena of life, both in health and disease, to the action and various conditions of the solids; the humoral pathology became then completely exploded by the speculations of the solidists. A more careful and impartial investigation, however, of the properties and uses of the various constituent parts of the animal economy in modern times, has been followed by the adoption of more comprehensive views of the operations of life; and it is now satisfactorily proved that the animal fluids, and particularly the blood, exercise an influence fully equal, if not superior, to that of the solids. In consequence of the imperfect state of animal chemistry, no very satisfactory results have yet been obtained from the analysis of the blood in disease. There can be no doubt, however, from numerous recent observations,

* Wilson Philip on the Vital Functions, c. v. p. 119.

* Andral, Pathological Anatomy, p. 660.

that it presents in many diseases a variety of remarkable changes in its physical characters: we must refer the reader for an account of these to the article *BLOOD, MORBID STATES OF THE*. Various alterations have also been discovered both in the chemical composition and physical properties of the other animal fluids as the effect of disease, and the *HUMORAL PATHOLOGY* is beginning to obtain, once more, the degree of attention to which, within rational limits, it is unquestionably entitled.

The blood has at all times been considered the chief support of life, and on this account, according to many, the seat of the vital principle. This is an opinion recorded in the most ancient books. We find in the Old Testament the following remarkable declarations of the inspired writers on this interesting point: "But flesh with the life thereof, which is the blood thereof, shall ye not eat."* "For the life of the flesh is in the blood." "For it is the life of all flesh; the blood of it is for the life thereof; therefore I said unto the children of Israel, Ye shall eat the blood of no manner of flesh, for the life of all flesh is the blood thereof."†

This opinion was embraced by Harvey, and in modern times has been warmly advocated by John Hunter. He considered, like some of the ancients, the principle of life to be a kind of distinct agent, independent of the conditions of matter, and endowed as it were with consciousness; he believed, however, "this principle to reside chiefly in the blood, and made a great many ingenious experiments tending to support this opinion. Hunter's arguments in favour of the independent vitality of the blood were its property of spontaneous coagulation and of assuming under certain circumstances the most complete organization. When blood is drawn from the vessels, the globules, which consist of pure fibrine, are attracted together and disposed to arrange themselves in lines or fibres, constituting the crassamentum. This fibrous arrangement bears a great analogy to the fibres of muscles, which consist also chiefly of fibrine.‡ Many causes of sudden death, such as lightning, the bites of venomous animals, some acrid and narcotic poisons, by which the nervous action is suddenly paralysed, have also the remarkable effect of suddenly changing the composition of the blood, preventing its coagulation, and rendering it incapable of supporting life. Under similar circumstances the muscles are also found relaxed and incapable of being excited by the

accustomed stimuli. These facts have been supposed by Hunter to prove an identity between the property of muscular contraction and that of the coagulation of the fibrine:* this idea seems to be further supported by the circumstance of the chemical composition of the fibrine and of muscle being nearly the same.

There have been many speculations on the cause of the spontaneous coagulation of the blood, some ascribing it to its death, and others, like Hunter, to its life, whilst some have attributed it to the escape of carbonic acid gas. The remarkable property of spontaneous organization which has been so frequently observed in coagula of blood seems directly opposed to the idea of its coagulation being the effect of its death; on the other hand, if blood is frozen and then thawed, it coagulates the moment it becomes liquid. We must admit that the blood was dead when frozen, and its coagulation after being thawed cannot therefore be reasonably attributed to its life.† The opinion of the coagulation depending on the escape of carbonic acid, which has been advanced by Sir C. Scudamore, is proved to be equally fallacious by the fact that no carbonic acid has been detected in the blood by the most accurate chemical analysis. Dr. Stevens has attempted to prove that the fibrine partly owes its fluidity within the body to the circumstance of being held in solution by the saline substances contained in the serum; that this saline solution, together with the influence of the living principle and of constant motion, contributes to preserve its fluidity in the vessels, but becomes insufficient to hold it in solution when removed from the body. The insurmountable objection, however, to this hypothesis is, that fibrine is found to be totally insoluble in solutions of neutral salts. Dr. Bostock's explanation of this property of the blood appears to us on the whole the most rational. He states in his valuable *System of Physiology*: "Perhaps the most obvious and consistent view of the subject is, that fibrine has a natural disposition to assume the solid form when no circumstance prevents it from exercising this inherent tendency. As it is gradually added to the blood, particle by particle, while the fluid is in a state of agitation in the vessels, it has no opportunity of concreting; but when it is suffered to be at rest, either within or without the vessels, it is then able to exercise its natural tendency. In this respect the coagulation of the fibrine of the blood is very analogous to the formation of

* Genesis, ix. 4.

† Leviticus, xvii. 11-14. This is the reason of the Jews refusing at the present day to eat the flesh of any animal which has not been bled to death, and of their having their own butchers.

‡ Dr. Hodgkin, having made numerous microscopic observations on the minute structure of various tissues and on the composition of some of the animal fluids, denies that the particles of the blood have a globular form, and gives a description of them totally different from that of preceding physiologists. (Catalogue of the preparations in the anatomical museum of Guy's Hospital, observations on section xi.)

* Dr. Stevens, who has made many experiments on the coagulation of the blood, mentions the following remarkable fact: "If at a certain period after the coagulation has commenced, we add muriate of soda or a saline solution to the coagulating blood, the moment that the fibrine feels the stimulus of the salt, the whole of it becomes suddenly solid; and I have seen the fibrine of inflammatory blood, which had been drawn during the hot stages of the marsh fever, contract on the application of salt with almost as much rapidity as the muscles, when we apply the same stimulus to the fibres in the living body."—Stevens on the Blood, p. 183.

† Elliotson's Lectures, Med. Gazette, Dec. 1831.

organized solids in general, which only exercise their property of concreting or coalescing under certain circumstances, and when those causes, either chemical or mechanical, which would tend to prevent the operation, are not in action.*

But the great argument in favour of the vitality of the blood is its property of spontaneous organization. When the fibrine and albumen are exuded in the form of coagulable lymph, it frequently happens that, although not in immediate contact with any of the surrounding solids, bloodvessels are seen shooting in every direction through the mass of concrete lymph, and it is gradually transformed into a new and perfectly organized living solid, having bloodvessels, lymphatics, and nerves, and performing all the functions of an original texture. The blood and the solids, when submitted to chemical analysis, are found to consist of the same proximate principles, and a similar analogy is observed in their physical structure, both consisting of globules variously united; these different circumstances made Borden apply to the blood the expressive appellation of liquid flesh, *une masse de chair coulante*.

It must, therefore, be admitted that the blood contains within itself the elements of organization, whether or not it be the exclusive seat of the vital principle. The powerful influence of the blood on the vital properties is further proved by the fact that the degree of vigour and activity of animal life depends in a great degree on the qualities of this fluid. If the blood contains a large portion of fibrine and red matter, the animal presents every sign of florid and exuberant health, and is predisposed to inflammatory affections: when the crassamentum of the blood is deficient and pale, and the serum preponderates, a languid state of health is the consequence, and a predisposition to diseases of debility. These opposite qualities of the blood are observed to depend in a great measure on its being brought into contact with either an ample or deficient supply of oxygen, provided always that a due quantity of nourishment is also received through the digestive organs. The vigour and activity of life can thus be partly estimated by the quantity of oxygen consumed, and also by the consequent degree of development of the animal temperature. This has led some to conjecture that oxygen was the principle of life; it can scarcely, however, be considered in any other light than that of a secondary agent; for if oxygen did not meet in the living body with some specific power modifying its action, there is no satisfactory reason why its influence on living animal matter should lead to results differing so remarkably in many respects from those it is observed to produce on inanimate matter.

Theory of inflammation.—After the phenomena of inflammation had for a long period been referred to a vitiated state of the fluids,

and to mechanical or chemical causes, pathologists began to perceive the impossibility of giving a rational explanation of all the morbid changes that mark the inflammatory process by any supposed state of the blood alone, and turning their attention to the condition of the vascular system, they fixed on an increased action of the bloodvessels as its proximate cause. It was found difficult, however, to reconcile the swelling of inflammation, which necessarily requires an increased capacity of the vessels, with the notion of an augmented vital action, which would imply an increase of their contraction. Boerhaave endeavoured to solve the difficulty by attributing the swelling and obstruction to a change in the texture of the blood itself, which, he imagined, became more thick and viscid, acquiring what he called a state of *lentos*; he supposed also that the increased action of the arteries forces the larger particles of the blood into vessels too small to receive them, which constituted the *error loci* of the mathematical pathologists; they conceived that the structure of the globules was very complicated, each red one consisting of six serous, and each serous of six lymphatic globules, for the conveyance of which, vessels of three different kinds and sizes were provided as channels of communication between the arteries and veins, so that if a globule got into a wrong vessel, it might obstruct all those behind it.

For this mechanical theory of Boerhaave, Cullen substituted his hypothesis of spasm and constriction of the small vessels, which, he believed, was sometimes the effect of direct debility, and connected with a diminished energy of the nervous power of the whole system arising from the action of certain deleterious causes on the brain. The necessary consequence of this general spasm of the extreme vessels was a reaction of the heart and large vessels, which had the effect of solving the spasm; this was his theory of idiopathic fever. He conceived also, as another principle in the pathology of inflammatory affections, that there was a peculiar condition of the whole vascular system, which predisposed to and might be induced by local inflammation, and which constituted what he termed the *diathesis phlogistica*; that this consisted in an increased tone or contractility of the muscular fibres of the whole arterial system, which existed generally in persons of the most rigid fibres. The obstruction of the blood in inflammation was thus attributed to spasm; but it was obvious that a state of spasm would be directly exposed to tumefaction; and that, if the first effect of local stimuli were spasm, the very reverse of swelling and redness would take place, the blood being expelled from the vessels of the part, as is seen in convulsions, where it is driven from the surface to the centre of the body; that if also the spasm were the consequence of a previous congestion of the vessels, this congestion should be received as the proximate cause, and the spasm merely as an effect.

Although there exists, no doubt, a habit of

* Elementary System of Physiology, vol. i. p. 444.

body corresponding to the *diathesis phlogistica*, which may predispose to inflammation, it is likewise satisfactorily proved by general experience that inflammation occurs much more frequently in constitutions characterised by lax, mobile, and irritable, than firm and rigid fibres; the inflammatory diathesis cannot, therefore, be always considered synonymous with the diathesis phlogistica of Cullen.

The great difficulty in all the theories of inflammation having been the manner of reconciling the increased action of the vessels, which supposes an increased contraction and consequently a diminished capacity, with the swelling which requires an augmented diameter of the inflamed vessels, several pathologists have had recourse to another hypothesis, by which the idea of increased action is set aside, and local inflammation is attributed to a diminished action of the vessels. This hypothesis was originally proposed about the middle of last century by the Italian physiologist Vacca, and first advocated in this country by Mr. Allen of Edinburgh. According to him the redness, heat, pain, and tumour are to be ascribed to an increased quantity of blood which the vessels contain in consequence of their relaxed state; he attributes those symptoms which had been usually accounted for by increased action, to this partial stagnation of the blood, together with a kind of struggle between the loss of power in the part, and the unusual stimulus to which it is thus exposed.*

This view of the subject had been adopted in a modified form by John Hunter, who supposed inflammation to be a disturbed state of parts which requires a new but salutary mode of action to restore them to their healthy state; inflammation is therefore rather to be considered a salutary operation than a disease. He describes the act of inflammation as an increased action of the vessels, which at first consists simply in an increase or distention beyond their natural size, this increase apparently depending on a diminution of the muscular power of the vessels, at the same time that the elastic power of the artery is increased in the same proportion: this is, therefore, something more than simply a common relaxation, and Mr. Hunter calls it an act of dilatation—an hypothesis, however, devoid of proof. He says that, owing to this dilatation, there is a greater quantity of blood circulating in the part, and that it passes more rapidly through the vessels; the swelling is also partly produced by an extravasation of coagulable lymph with some serum, the lymph differing from the common lymph in consequence of passing through inflamed vessels.

The theory of a diminished action of the vessels was embraced also by Dr. P. Wilson,† Dr. Thomson, and Dr. Hastings, who all performed a variety of experiments in its support. Dr. P. Wilson first shewed that he could create increased action in the capillaries without exciting inflammation; but whenever

inflammation was established, he found the capillaries in a state of preternatural distention and debility; whilst the larger arteries experience an increase of action, which, by keeping up a strong *vis a tergo*, tends to augment the inflammation. If, however, the inflammatory action continues, the vessels immediately preceding the inflamed capillaries become also distended, and consequently debilitated: in short, according to Dr. P. Wilson, inflammation seems to consist in the debility of the capillaries, followed by increased action of the larger arteries, and is terminated by resolution, when the capillaries are so far excited, and the larger arteries so far weakened by the preternatural action of the latter, that the power of the capillaries is again in due proportion to the *vis a tergo*. He refers many of the more general phenomena of inflammation to the sympathetic influence of the nervous system.

Dr. Thomson draws from his experiments inferences rather at variance with those of Dr. P. Wilson, for he conceives that it is not necessary to the establishment of Mr. Allen's hypothesis to admit that the capillary circulation is slower in inflammation. "I am inclined to believe," says Dr. Thomson, "that a diminished velocity of the blood in the capillary branches is by no means a necessary, constant, nor even the most common effect of incipient and moderate degrees of inflammation."‡ He considers that the velocity is sometimes increased and sometimes diminished.

This difference in the statements of these two gentlemen induced Dr. Hastings to repeat their experiments, in order, if possible, to reconcile them: and he came to the following conclusion: "that certain stimuli applied to living parts produce an increased velocity of the motion of the blood and a contraction of the bloodvessels. During this state of excitement the part affected is so far from giving any thing like the appearances of inflammation, that the size of the vessels is diminished and the part paler. But if the stimulus be long-continued or increased in power, the small vessels, which in the natural state admit only one series of globules, become so dilated as to allow an accumulation of a much less fluid and redder blood in them, which loses its globular appearance, and moves much more slowly than that which previously passed through these vessels: the part now appears inflamed; if the stimulus be removed, the vessels do not soon regain their original state; time is necessary to allow them to recover their contractile power, so as to prevent the impetus with which the blood is propelled by the heart and large arteries from keeping up the dilated state of the capillaries." "It may be logically inferred, therefore," says Dr. Hastings, "that inflammation consists in a weakened action of the capillaries, by which the equilibrium between the larger and smaller vessels is destroyed, and the latter become distended." Dr. Hastings argues that Dr. Thomson's belief in the excitement of the capillaries in some cases of inflammation, arises from his having

* Thomson's Lectures on Inflammation, p. 68.

† Treatise on Febrile Diseases.

‡ Op. cit. p. 75.

denominated a state of inflammation that which ought not to be so called, being only that temporary excitement of the capillaries generally preceding their debility, which is inseparable from inflammation.*

The late Dr. Parry, of Bath, whose researches on the functions of the vascular system have deservedly attracted so much notice, necessarily rejected the opinion of diminished action of the capillaries in inflammation, since he denied that the capillaries possess any independent muscular power, asserting that the blood was propelled through them by the contraction of the heart alone. He attributed inflammation to an increased momentum of the blood in the part affected, and therefore to an increased passive action of the capillaries. This hypothesis has been strongly advocated by Mr. James, of Exeter, in his treatise on inflammation. The facts brought forward, however, in support of the opinion that the extreme vessels possess a contractile power, appear to us so convincing and satisfactory as to set aside completely the opposite theory.

In all the preceding theories the contractility of the vessels only seems to have been taken into consideration, whilst the other great vital property—the sensibility of the part—has been almost entirely overlooked. Sufficient attention also does not seem to have been paid either to the changes of the blood or to the modifications both in the structure and functions of the part which characterize inflammation, and vary considerably in its different periods. Each theory appears to contain much that is true, especially that of Dr. Hastings, but to be constructed on too narrow a basis, incapable of satisfactorily accounting for all the facts.

The experiments have been repeated with care by several continental pathologists, and especially by Gendrin† and Kaltenbrunner‡. The former has investigated with considerable attention the whole pathology of inflammation, and has given a luminous description of several important phenomena, especially those of supuration; he adopts the opinion of an increased action of the vessels being the primary cause of inflammation. Kaltenbrunner's microscopic researches have been much more minute, accurate, and conclusive than those of any of his predecessors, and afford an excellent specimen of experimental inquiry conducted in a truly practical and philosophical spirit: he confines himself, however, to a description of the obvious phenomena without entering upon any theoretical reasoning. As the limits of this article do not admit of a separate account of experiments, we shall give a description of the different stages of the inflammatory process, as deduced chiefly from the results of Kaltenbrunner's observations, and shall state, as we proceed, the conclusions we have adopted respecting the nature of the phenomena of inflammation.

When a stimulus is applied to a living part, the first effect produced is an excitement of the sensibility of the part, and, with some exceptions, a consequent degree of pain: this, however, soon subsides, if the irritation be only slight or temporary; but when the effect of the stimulus is either severe or prolonged, the contractility of the vessels of the part is next roused into increased action; the necessary result of this morbid excitement of the sensibility and contractility of the vessels is a more rapid flow of blood to the part, which, acting itself as a stimulus, tends still more to quicken the circulation: there is consequently a considerable influx of blood in all the vessels, arteries, capillaries, and veins, to the amount, perhaps, of double or triple the usual quantity; and as the vessels of the surrounding parts do not partake of this increased action, the blood of the irritated vessels is not carried off as quickly as it arrives, and must inevitably soon accumulate. Bloodvessels, like all other contractile and elastic tubes and tissues, are capable of having their capacity and other dimensions increased within certain limits, without any sensible diminution of their power of contraction or of their mechanical strength; the stimulated vessels thus adapt themselves to the increased flow of blood by becoming enlarged, whilst they still preserve their control over the circulating current. Vessels, which in their natural state were scarcely perceptible, owing either to the admission only of a thin colourless blood or to their extreme tenuity, now become dilated and visible, a red and more viscid blood being propelled through them. Boerhaave and the mathematical pathologists had accurately noticed this admission of the red globules into vessels from which they were previously excluded, calling it an *error loci*.

The pressure of the blood is sometimes greater, however, than the vessels are able to resist; this more particularly happens when the irritation has extended to the larger arterial branches and to the heart, so as to excite a strong *vis a tergo*. The strength and action of the smaller vessels diminish as their distention increases; the circulation, which was at first accelerated, now becomes gradually slower, and may continue in a languid and oppressed state for a considerable length of time without being completely interrupted. Under these circumstances the healthy functions of the part are necessarily more or less impeded; the blood ceases to undergo its usual change from arterial to venous; the red globules, which were before confined to arteries, are now seen circulating in the small veins; these globules are more numerous and of a more vivid red; the viscosity and coagulability of the blood seem augmented by a decrease in the proportion of its serum; and the globules, having a tendency to unite together, become less distinct; the functions of nutrition and secretion are also partially or wholly suspended.

The part affected now presents the following morbid conditions: an increased influx of blood and turgid state of the vessels—some degree of swelling and pain—an increase of heat, and, in certain textures, of redness, which

* On Inflammation of the Mucous Membrane of the Lungs.

† Hist. Anat. des Inflam. tom. ii.

‡ Répert. Général d'Anatomie, et Physiol. Path. tome iv. p. 201.

disappears on pressure—the circulation either much quickened, or slow and embarrassed, with suspension of the healthy functions. These changes constitute a distinct period of disease, which has too often been mistaken for inflammation, but which it is highly important should always be distinguished as its previous stage only, and may be named *active congestion*. The existence of a morbid state, such as we have just described, is of common occurrence in a variety of diseases, and frequently subsides without passing into inflammation. When, however, by the increase of the diseased action, inflammation supervenes and is fully developed, a series of perfectly new and distinct morbid phenomena are observed, which will be presently noticed.

Congestions are sometimes formed, however, in a different manner. If the vessels of a part (arteries and veins) have been much weakened, as happens from a variety of causes, or if there be any obstruction to the return of the blood through the veins, an accumulation of blood, a languid embarrassed circulation, vascular turgescence, and several of the other symptoms of congestion, will necessarily follow, without requiring the previous application of a stimulus. The increased influx of blood sometimes proves a sufficient stimulus to excite a reaction in the vessels of the part, an accelerated circulation, and a state of active congestion, which may lead to inflammation. In other cases, however, no reaction takes place; the vessels remain in a turgid, loaded, debilitated condition, with a languid circulation, constituting a *passive* form of congestion. The characters of these and of some other varieties of congestion will be more fully examined in another place.

When congestion begins to subside, a diminution in the activity of the circulation and influx of blood is first observed at the circumference; the blood seems to reflow from the circumference towards the centre; the swelling, pain, heat, and other symptoms gradually disappear. The resolution of congestion is generally promoted by critical discharges. In some cases there is a slight exhalation of a serous or sanguineous fluid either on the surface of the part or in the interstices of the vessels; an exudation of small red scales is sometimes perceptible through the microscope. The congested vessels may be relieved by a profuse flow of the natural secretions, as is frequently seen on the surface of mucous and serous membranes, or else by spontaneous hemorrhage.

It is important not to mistake for congestion or inflammation various changes in the state of the circulation that sometimes immediately follow the application of certain stimuli to a living part, and are only of a temporary nature. Simple compression is sufficient to cause a momentary interruption of the circulation and stagnation of the blood; the application of muriate of soda to the web of a frog's foot is followed by a diminution of the velocity or a complete stoppage of the circulation, and a remarkable increased redness of the blood; the immediate effect of a slight wound is an accelerated cir-

culation, an increased flow of blood, redness, and other symptoms of incipient congestion; alcohol produces similar results, and sometimes a constriction of the vessels. All these changes, however, are only the immediate consequences of the mechanical or chemical action of the stimulants on the vessels, and of temporary nervous irritation, and do not of themselves constitute congestion or inflammation. When the irritation is slight, the increased activity of the vessels and influx or stagnation of blood soon disappear, after the removal of the irritating cause; but if the irritation has been prolonged or severe, and particularly if it has occasioned any extensive and permanent injury to the texture of the part, a reaction takes place soon after the changes just described have subsided, and a new process, *essentially vital*, is set up, intended to remove the irritating cause, or repair the injury it has inflicted; the circulation is consequently observed to assume again an increased activity, and the regular symptoms of congestion or inflammation are gradually developed. This is an important circumstance attending the process of inflammation, which had been noticed by Dr. Hastings, but has been since more clearly and accurately defined by Kaltenbrunner; and mistakes have no doubt been made in several accounts of the theory of inflammation from its having been overlooked.

The interval between the application of a stimulant and the development of the regular congestive or inflammatory process, may be considered as a period of *incubation*. The duration of this period is very variable; on the edges of wounds, where it is well marked, it may last several hours. The inflammation, however, does not always shew itself in the part to which the exciting cause has been first applied, but in some other more or less remote; a variety of medicinal and poisonous substances applied to the external or internal surfaces of the body, frequently excite irritation or inflammation either in some of the secreting surfaces and organs, in the brain and nervous system, or in the heart and large vessels; and they produce this effect either by being absorbed and conveyed with the blood, or by their direct impression on the nervous system. Some animal poisons excite inflammation both in the part to which they are immediately applied, and in remote organs, as happens with the virus of hydrophobia, variola, &c. This secondary or sympathetic inflammation is not always the effect of irritating but frequently of depressing agents, acting on distant parts; a state of debility, or the suppression of the functions of one organ, becomes thus a very common cause of congestion and inflammation in another. All causes that operate in lessening the circulation on the surface or at the extremities of the body tend to produce determinations of blood, and an inflammatory reaction in some of the internal organs. The slow and long-continued influence of such causes often gives rise to continued fever; or, when more sudden and active, to local inflammation. In all these cases a greater or less period of time may elapse between the application of the ex-

citing cause and the development of the disease; this is particularly the case with certain animal poisons, which may remain for some time circulating with the blood before they produce their specific effects. The consideration of the symptoms, duration, and treatment of the period of incubation, embraces some highly interesting questions, especially with respect to contagious diseases, as Dr. Marsh has shewn in an excellent essay on this subject, published in the Dublin Hospital Reports.

We are next to consider the morbid changes that occur when congestion passes into true inflammation. If the action of the irritant be either violent or repeated, the appearances characteristic of active congestion extend from the centre to the circumference over a larger surface; the swelling and other symptoms increase in intensity, until the vessels are at last so gorged with blood that the strength and activity of their contractile fibres are overpowered; the vessels become therefore less and less able to resist and propel the current of blood, until its motion completely ceases; the blood then stagnates in the vessels, where it undergoes certain changes in its composition. This stagnation of the blood does not take place in the whole extent of the inflamed surface at once; the circulation first becomes slower, and the blood stagnates in some of the vessels at the centre; it then stops in others, forming sometimes several small nuclei of stagnation, which decrease in number and size towards the circumference, where the circulation continues more accelerated, and the part is in a state of active congestion. These changes occur first in the weaker vessels (the capillaries and veins), and afterwards in the arteries.

The following are the alterations observed in the composition of the blood; as the heat and other symptoms increase, the blood becomes less serous, more viscid and coagulable, and of a more vivid red; its course is altered, and a number of the globules are seen agglutinating together so as to form minute cylindrical clots; these are pressed in small columns from the capillaries into the veins, and move slowly in various directions, oscillating backwards and forwards until they become motionless; the blood is then evidently decomposed, so that the globules and serum can no longer be distinguished from each other, and it presents a red homogeneous coagulated mass, a part of the serum being generally expressed and effused around it. Motion, it is well known, is indispensable to the preservation of the globular appearance of the blood. A momentary vacuum is sometimes observed in the vessels between these coagula.

Another important occurrence, at this stage of the inflammatory process, is the bursting of a number of the over-distended vessels, and the extravasation of the blood in the surrounding texture, from which it is inferred that a diseased state of the coats of the bloodvessels is one of the immediate effects of inflammation, not less important than the changes in the composition of the blood. The acute inflammation of a large bloodvessel is characterized by redness, rugosity, thickening and

softening of its internal membrane; the coagulated blood either adheres to it immediately, or through the intervention of a layer of effused lymph; the middle and outer coats are also injected, thickened, and much more friable; and the whole texture of the vessel having lost its density and elasticity, is very easily torn. We may safely conclude that the inflammation of smaller vessels will be attended with nearly similar changes of structure.

The points of stagnation are easily distinguished by their more vivid red colour, and the redness differs from that of congestion in not being removed by pressure. The colour varies, however, considerably according to the intensity of the inflammation, the texture of part, and the nature of the exciting cause. In very intense inflammation there is a livid red, which becomes black in gangrene. Muriate of soda produces a dark purple red; alcohol a bright clear red, and muriate of mercury a brown dusky red. The rapidity with which the course of the blood is interrupted, the number and extent of the points of stagnation, depend likewise on the same causes. When the inflammation is intense and the circulation very rapid, the blood does not stagnate so soon; but the points of stagnation are more numerous and extensive. When alcohol is applied to the web of a frog's foot, the circulation is quickened, and after some time a few points of stagnation may be seen; a fresh application of alcohol to the same part is followed by an increased activity of the circulation; the small coagula previously formed are sometimes again set in motion by the increased force and velocity of the current of blood, and the obstruction of the vessels is thus removed. Any new interruption in the course of the blood will take place more slowly, in proportion as the activity of the circulation is kept up by fresh applications of alcohol. The same results follow the infliction of wounds of different degrees of severity, and the application of other stimuli. It has been ascertained by Kaltenbrunner, that in highly vascular organs, in which the circulation is very rapid, such as the lungs and the mesentery, more time is required for the perfect development of the inflammatory process, than in organs whose circulation is more slow, such as the liver; but that when the inflammation is once established, it is much more intense in the former than in the latter. In cold-blooded animals, the susceptibility to the influence of stimulants being comparatively feeble, the circulation is only moderately increased under their application. Inflammation is on this account quickly established by the stagnation of the blood, but seldom violent. It may be stated as a general principle, that the rapidity with which the inflammatory action is fully developed is in the *inverse* ratio, and the violence and extent of the inflammation in the *direct* ratio, of the activity of the exciting cause.

It has already been observed that the blood ceases to undergo its change from arterial into venous during congestion and inflammation, and that the functions of nutrition and secretion are also completely suspended. There is

sometimes also an apparent absorption of certain portions of the inflamed tissue; the stellated black spots of the frog's web gradually disappear, when the blood is kept for some time in rapid circulation through its vessels, and small particles of the pigmentum may be seen carried away by the current of the blood. The fat of the mesentery and the earthy matter in bones is removed in a similar manner.

Another striking phenomenon is the formation of new canals or vessels by globules of blood bursting through the sides of a vessel and forcing a passage for themselves through the cellular texture into another vessel. A considerable number of new canals are sometimes formed by this mechanical process, through which the blood continues to circulate. This interesting phenomenon has been frequently observed by Kaltenbrunner in the inflamed mesentery of the rabbit. We have not had an opportunity of verifying it; but it is easy to conceive a number of the small delicate cells of the cellular tissue being united together by the forced passage of the blood, and forming new tubes. This is strictly analogous to what takes place in the organization of coagulable lymph, where the globules of the blood may be seen forming new passages for themselves by shooting in every direction through the mass of soft lymph.

Beside the extravasation of blood into the parenchyma of the inflamed part already noticed, there is also a certain degree of interstitial effusion. In all animal tissues, during health, there is a constant exhalation of a fluid in the form of vapour between their fibres or laminae. Gendrin gives the following description of the section of an inflamed part. Towards the centre it exhibits an infiltration of nearly pure blood, disposed in small coagula, and having sometimes a globular appearance, these coagula being surrounded with a gelatinous fluid. In some cases, instead of red blood, there is found a yellowish semi-concrete fluid resembling fibrine, and when inspected with the microscope, apparently partly composed of globules. On the outside of this concrete deposit, there is a reddish fluid half serous and half gelatinous, containing only very few globules; and quite at the circumference there is found pure œdema, with which almost all inflamed parts are more or less surrounded.

We have thus given an account of the various local effects which have been ascertained by observation and experiment to follow the application of stimulants to the living body, from the slightest degree of irritation to the perfect development of inflammation. It has been shewn that a morbid excitement of the sensibility is the first effect arising from the application of stimulants, and that from which all the other phenomena of inflammation seem to derive their origin: the diseased action, moreover, never completely subsides until the sensibility has been restored to its normal state, so that this morbid condition of the sensibility may be considered as operating in a manner strictly analogous to the *ideal thorn* of Van Helmont. Other morbid agents act in

depressing the sensibility and causing a diminished vascular action and a stagnation of blood, which is often followed by inflammatory *reaction*. This primary influence of the sensibility over the phenomena of inflammation is a circumstance which does not appear to have received hitherto the degree of attention it deserves. It will be seen hereafter that nearly all the modifications of inflammation may be traced to some of the infinite variety of morbid conditions which the sensibility is capable of assuming. The intimate connection between the vascular and nervous functions, and the influence especially of the nervous system over the circulation of the extreme vessels, strongly corroborate the accuracy of the preceding views.

In considering the action of stimulants on the animal economy, it appears also that sufficient attention has not been paid to the fact that they excite a series of distinct morbid changes, passing gradually into each other, and whose characteristic differences have not been hitherto well defined. Genuine inflammation is never established instantaneously, but is always preceded by certain deviations from healthy action, which constitute preliminary stages. We conceive, therefore, with Kaltenbrunner, that the morbid changes which lead to inflammation may be divided into the three following periods.

1. A period of *incubation*, variable in its signs and duration. A better knowledge of the pathological condition of the system during this period might lead to the adoption of means capable of preventing the development of disease, and of destroying it as it were in embryo.

2. A period of *congestion*, characterized, first, by an increased activity of the vessels and influx of blood—various degrees of turgescence, swelling, heat, redness, and pain—interruption of the healthy functions of the part—and, secondly, as the congestion increases, a laboured slow circulation arising from the over-distention of the vessels, and increased thickness and viscosity of the blood. There is yet, however, no change of structure in the part, nor formation of new products; the circulation, although slow, is still carried on or only very partially interrupted, and the affection may subside by critical secretions and hemorrhage.

3. The period of *inflammation*, which is characterized by an entirely new order of morbid changes. The circulation is completely interrupted—the blood coagulates, clogs the vessels, and stagnates in several points of the inflamed part—the coats of the vessels are diseased—some of the vessels are ruptured, and there is extravasation either of blood or coagulable lymph in the parenchyma—lymph and serum are also exuded, and the deposition of these new products leads to a decided change of structure—the healthy functions of the part are completely suspended, and some of its constituents, such as the pigmentum and adipose matter, are sometimes absorbed—new vessels are also mechanically formed by the blood forcing itself a passage through the deli-

cate areolæ of the cellular texture. All these changes are attended with a considerable increase of the swelling, heat, redness, and pain.

Congestion and inflammation pass so gradually into each other, that they are necessarily always combined, and it may often be extremely difficult to draw an exact line of demarcation between them. The stagnation of the blood, effusion of blood, lymph, or serum, either by exudation or rupture of the vessels, the changes in the structure of the part, and formation of new products, may generally be considered, however, as the pathognomonic signs of inflammation. The interruption of the circulation and extravasation of blood are not sufficient of themselves to constitute inflammation, since they are observed to take place in many cases of local or general vascular debility, the very opposite of inflammation, as, for instance, in ecchymosis, scorbutus, &c. It is only when these symptoms have occurred in conjunction with a series of certain other morbid actions, both preceding and following them, that they can be said to indicate inflammation.

It is assuredly neither rational nor philosophic to apply to these varied morbid phenomena of the inflammatory process but the one hypothesis of either increased or diminished action. It appears also incorrect to describe vessels, which performed their functions efficiently during health, as affected with *direct* debility, because they are unable to perform double their usual labour with equal efficiency in disease, as is the case with the vessels of an inflamed part. It is impossible to deny that, unless under peculiar circumstances forming exceptions to the general rule, the action of the vessels is at first greatly and powerfully increased, and it is only when they become clogged and over-distended by an excess of blood, and by blood less thin and fluid than that which they contain in health, that being no longer able to contract, they become passive. Direct debility of the small vessels cannot, therefore, correctly be admitted as the primary cause of inflammation, since we only see debility occur as a *secondary effect*. Weak and relaxed vessels are themselves susceptible of increased action, and often in a much greater degree than vessels in the opposite state; for it is well known that constitutions in which the fibre is lax and delicate are generally characterized by a much higher degree of mobility and irritability, and are much more predisposed to inflammation than constitutions endowed with a more firm and rigid texture of the solids. While delicate and sensitive vessels are easily roused into excessive action, they are less able to sustain it, and are, therefore, more readily overcome by the increased flow of blood, and more quickly affected with inflammation: this is fully exemplified in infants. But although the weak and delicate structure of vessels predisposes them to inflammation, still increased action is a primary condition necessary in most cases to its development. We may also add, in opposition to the hypothesis of direct debility of the vessels, that the exciting causes and treatment of inflammation coincide better

with the idea of excessive than of defective action.

The following summary gives a condensed view of the series of morbid changes that have been described as occurring in the inflammatory process:—Increased sensibility of the part, followed by increased action of the vessels—quickenened circulation—increased influx of blood—dilatation of the small vessels and capillaries—admission of red blood into vessels previously colourless—turgescence—swelling—and sometimes a slow and embarrassed circulation—*active congestion*. If the diseased action continues, the contractility of the vessels is paralysed by their over-distention—the blood stagnates and undergoes changes in its composition—disease of the coats of the blood vessels—rupture of many of the vessels—extravasation and effusion of blood, coagulable lymph, and serous fluid—changes in the structure of the part affected—*inflammation*.

This view of the theory of inflammation has the advantage of accounting in the most satisfactory manner for many of the modifications of common inflammation. The exciting cause may be of such a nature as at first to stimulate both the sensibility and vascular contractility of the part, and induce a degree of congestion. But if its action be increased beyond a certain point, it may have an opposite effect in lessening both the sensibility and vascular contractility, and inducing a state of torpor; the blood will then stagnate, not from excessive irritation and over-distention of the vessels, but in consequence of their deficient vitality and relaxed condition. This is frequently the mode of operation of cold, and of several stimulating narcotics and animal poisons, which excite a peculiar form of low sub-acute inflammation, requiring a specific mode of treatment.

In another variety of inflammation, the sensibility is directly weakened or completely paralysed, without previous irritation. There is at first no increased action of the vessels, or greater influx of blood; but the contractility and sensibility of the vessels being lowered or nearly paralysed, the current of the blood becomes extremely languid, and finally stops; reaction is generally excited in this case by the *vis medicatrix nature*, and a low kind of inflammation supervenes, which may terminate rapidly, either in unhealthy ulceration or gangrene. The living parts are then separated from the dead by a line of acute inflammation. The nervous power and vascular action of a part may be impaired or destroyed, as just described, by causes acting more immediately through the medium of the nervous influence, such as electricity, galvanism, intense cold, some very active narcotics, the ligature of large nerves, &c.; or by noxious substances taken into the blood, and materially altering its properties; or else by a deficient supply of arterial blood in consequence of the ossification and other organic diseases, or the pressure or ligature of large arteries. It remains, however, yet to be decided, whether the blood may not be considered the sole vehicle of all morbid agents, without its being

necessary to have recourse to nervous agency in order to explain their effects. The great rapidity of action of some deadly poisons seemed to favour the opinion of the nervous influence being exclusively the medium through which they operate. It would appear, however, from some recent observations, that morbid principles can be conveyed by the blood to remote parts of the body much more rapidly than was formerly imagined. This is an intricate but highly interesting question, requiring to be submitted to further investigation.

The preceding theory of inflammation enables us also to give a satisfactory explanation of the opposite mode of treatment often required in the different stages and modifications of inflammation. It is thus easy to explain, for instance, why local and general depletion are useful in the first stage of inflammation, in lessening the irritation and increased action of both the nervous and vascular systems; in reducing the quantity of the blood, and thus preventing the over-distention and obstruction of the vessels, and the extravasation consequent upon their rupture; in lessening, moreover, the viscosity, thickness, and coagulability of the blood, which is the constant effect of free depletion: why, on the contrary, in cases in which the exciting cause has more directly weakened the nervous and vascular action of the part, as is the effect of cold and of a variety of poisons, stimulants may be required from the beginning:—how, also, stimulants, when cautiously used, may in the latter stages of inflammation assist in restoring the weakened or oppressed action of the nervous and vascular systems, and in this manner facilitate and hasten the elaboration and expulsion, or the absorption of the morbid products, by which means the sequelæ of the disease are removed:—and why, also, the application of a stimulus, different from that which produced inflammation, will sometimes bring on resolution.

Having followed the changes that attend the inflammatory process up to its full development, we proceed to trace them in its ulterior stages. Before the inflammation has reached its greatest height, and any considerable change of structure has taken place, it may gradually subside. The frequency of the circulation begins to decrease at the circumference, and there is a reflux of the blood towards the centre; there are critical exudations through the sides of the vessels, consisting of a thin serous or sanguineous fluid, poured out on the surface or in the cellular texture of the part, similar to those already described in congestion; there may be profuse exhalation of fluids on the secreting surfaces; the small coagula of lymph and blood contained within the vessels, or deposited in the parenchyma, are softened and removed, either by the impetus of the current of the blood within the vessels, or by interstitial absorption. The tumefaction, heat, redness, and pain, gradually subside: this is the most favourable mode of termination of inflammation, called resolution.

In more severe inflammation, when the texture of the part has suffered greater changes, it

is frequently restored to its healthy state, and the effects of the disease are removed by a different process, which leads to the formation of a new fluid called pus. For a long period suppuration was believed to be the result of a dissolution of the living solids after they had been broken down by inflammation, and pus was supposed to possess a corroding power, by which it continued the dissolution. These opinions were, however, completely set aside by the more rational theory of this fluid being formed by a process of secretion. The origin of this morbid fluid has been traced still further by Laennec and Gendrin, who consider suppuration as the result of a direct conversion of the coagulable lymph of inflammation, and of the fibrine of the blood, into pus. Laennec believed pus to be simply softened coagulable lymph; coagulable lymph is found by analysis to consist not only of the fibrine of the blood, from which it differs by its lesser consistency, but also of a small proportion of albuminous serum; it is supposed therefore to be formed of an intimate combination of the fibrine of the blood with a small portion of albumen, rendered more viscid and coagulable by the vital influence of the inflammatory action, and deprived also of the colouring matter. The opinion that pus is formed directly from the blood by the fibrine simply undergoing some slight modifications in its properties during inflammation, is supported by the following interesting experiments of Gendrin, which will require, however, to be repeated by others before the important conclusions to which they lead can be considered as fully established.*

If any portion of an artery or vein be included between two ligatures, the intercepted blood at first coagulates; a portion of the serum is absorbed; a slight degree of inflammation is excited in the inner membrane; the globules of the coagulum lose their colour; a thin stratum of coagulable lymph is deposited on the sides of the vessel, forming a medium of adhesion between the clot and the internal membrane; and the clot itself becomes gradually organized. There is in this instance adhesive inflammation, and organization of the blood, without suppuration. But if a stimulating injection be thrown into a portion of a bloodvessel, the circulation having been previously suspended by means of ligatures, and if, after it is withdrawn, blood be again admitted and retained within the vessel, a more violent degree of inflammation is excited on the internal membrane, instead of the coagulable lymph, and the entire clot becoming organized, they are observed to acquire less consistency; small yellow globules are soon perceived between their layers, and they gradually undergo a more or less complete conversion into genuine pus. It is stated that these successive changes can be very distinctly watched with the aid of the microscope, and that they may sometimes be observed in cases of aneurism and phlebitis. If blood taken from one dog be injected into

* *Histoire Anatomique des Inflammations*, vol. ii. p. 470.

the cellular texture of the axilla of another, it soon coagulates, a slight degree of inflammation takes place, and the injected blood is gradually absorbed; but if a higher degree of inflammation is excited by any stimulating injection, or the passing of a seton, the blood, instead of being absorbed, is rapidly converted into pus: it would appear, therefore, that a certain degree of inflammation is indispensable for the transformation of extravasated blood or lymph into pus.

It is deserving of notice that venous blood appears to possess a greater tendency to conversion into pus than arterial, while the latter is much more disposed to become immediately organized; and likewise that suppuration is favoured by a high degree of inflammation, whilst immediate organization is more generally the result of moderate inflammation: these considerations point to a variety of important practical precepts.

Suppuration, however, is not merely the result of the conversion into pus of a mass of extravasated blood or coagulable lymph, but takes place both on the surface and in the interior of inflamed organs by a regular process of secretion, through the medium of vessels either previously in existence or newly formed. It constitutes in this manner a new function, which sometimes persists for a considerable period after the inflammation has subsided, as is seen in fistulous sinuses, chronic ulcers, setons, &c. Gendrin has minutely investigated the nature of this process by exciting violent inflammation in the web of a frog's foot and in the mesentery by means of a seton, the actual cautery, or boiling water, and watching its progress with the microscope. The following interesting account of the result of these experiments is favourable likewise to his opinion of the globules of fibrine being directly converted into globules of pus.*

After the inflammation has attained its height, the circulation remains for some time stagnant, the vessels and intermediate cellular texture being both filled with coagulated blood and lymph; the colouring matter gradually disappears, the part assuming more and more an opal tint; small yellow soft molecules may be seen interspersed through the coagulum, and some of them agglomerating in large globules evidently purulent. A slow degree of motion gradually becomes apparent by the oscillation of some of the globules in the old vessels; whilst a passage seems to be made for others through the mass of softened lymph by the formation of new canals, especially near the surface. It is stated, moreover, that the various alterations which the globules of the blood undergo during their conversion into pus can be distinctly followed by the eye, especially in the bloodvessels of the mesentery; that the globules are first seen corrugating themselves and separating from their colouring envelope; that they then lose their transparency, becoming, as they approach the edge of the wound where the irritation is the strongest, more opaque, larger, softer, and completely converted into purulent

globules. Small lacerated portions of the substance of the part are in some cases apparently dissolved by and carried along with the pus. The vessels soon become more distinct and numerous, and the circulation more regular, although it continues very slow as long as the vessels convey pus. As the swelling subsides by the discharge of the pus, the vessels in the centre re-admit red blood, and their circulation becomes more active. As soon as the suppuration ceases, a coagulable globular lymph of a pale flesh colour, and covered with red streaks, is exuded on the surface of the wound instead of pus; the red streaks are converted into vessels, by means of which the stratum of lymph becomes organized, and the cicatrization is completed. When suppuration is prolonged and rendered habitual by artificial means, the vessels secreting pus are increased in size and number, and assume a more regular action.

Gendrin concludes from his experiments that the conversion of the fibrine of the blood into pus takes place independently of the action of the vessels or of any vital influence of the inflamed part, and by a mere chemical process not yet well known. This is an opinion, however, which we think scarcely admissible, for it would be extremely difficult to account for the great varieties observed in the qualities of pus in different forms of inflammation, and especially for its *specific* properties in certain diseases, on any other principle than that of referring them to the vital influence of the diseased vessels, as at least one of their essential causes.

The preceding, which is the most simple form of the suppurative process, usually attends mild inflammation. In violent inflammation, when the parenchyma has been much lacerated by the extravasation of blood and coagulable lymph, instead of the pus being entirely collected in vessels, it accumulates towards the centre of the tumour, where it is mixed with loose fragments of cellular tissue and coagulated blood. When the loss of substance has been considerable, the circulation is only partially restored, and the parts destroyed may undergo a degree of putrid fermentation; the pus itself assumes a dark livid colour and an acid unhealthy character, and this leads to gangrene or sphacelus. Suppuration in this case takes place more by a process of decomposition than of regular secretion; it is a species of imperfect suppuration.

The alterations which the blood and other fluids undergo in different textures during inflammation, correspond in general to those just described as occurring in the cellular texture; they present, however, a few modifications, which we shall notice in this place, in order to give a complete and connected view of the nature of the inflammatory process.* When a serous membrane, as, for instance, the pleura, is slightly inflamed, there is, first, an effusion of a yellowish serous fluid, slightly viscid and alkaline, and consisting almost entirely of a small portion of albumen held in solution by water.

* See Gendrin, *op. cit.* Alterations des fluides, &c. vol. ii. p. 492, from which the facts contained in the following account have been partly derived.

* *Op. cit.* vol. ii. p. 477.

As the inflammation increases, the surface of the membrane is lined with a thin layer of a soft viscid substance of a greyish colour, consisting of a semi-transparent jelly, interspersed with small globules of a yellow tint, and characterized by the property of spontaneous coagulation. This coagulated substance increases in thickness, viscosity, and density with the inflammation, constituting on the third or fourth day a distinct plastic, laminated, pseudo-membrane. When submitted to analysis, this membrane is found to consist of fibrine with a small proportion of albumen, and corresponds in every respect with the coagulable lymph of phlegmonous inflammation; it is insoluble in water, otherwise it would be dissolved by the serous fluid contained in the cavity of the membrane, instead of adhering to its surface. The serous fluid poured out at this period of the inflammation loses its transparency, becomes turbid, viscid, and more alkaline; its albumen is considerably increased, and it deposits a greyish flocculent coagulable matter, exactly similar in its properties to false membrane, containing only a larger proportion of albumen and aqueous fluid. When the inflammation has lasted several days, the liquid assumes a yellow or greenish tint, and there is added to the coagulable lymph a yellow viscid matter, which is deposited in a pulverulent form, is soluble in alkalies when dried, and when examined by the microscope, presents all the appearances of globular pus. A large proportion of this last mentioned matter is formed in violent inflammation, giving the effused fluid a well-marked purulent appearance, and a quantity of pus is sometimes deposited, as pure and genuine as that coming from an abscess. The inflammation of all serous membranes is followed by similar results. In the inflammation of synovial membranes the viscid, oily, albuminous synovia is likewise converted into coagulable lymph or pus, according to the intensity of the inflammatory action.

The fluid secreted by mucous membranes consists, in health, of animal mucus held in solution by an aqueous fluid, and containing a small quantity of saline matter; the proportion of these ingredients varies in the different mucous membranes, and other elements are added to them in some, such as muriatic acid in that of the stomach, a sebaceous matter in that of the ear, &c. In active congestion or commencing inflammation, there is generally more or less increase of the natural secretion; it has in ophthalmia the appearance of thin viscid yellow mucus; in coryza it is more fluid and of a yellow white; in bronchitis it is transparent and viscid, like the white of an egg mixed with water; in diarrhoea it is very watery and copious, with white flakes floating in it; it is also more or less tinged with bile. In inflammation of the vagina and urethra it is thin, white, and transparent; in inflammation of the urinary bladder it is mixed with the urine, in which it floats in the form of viscid flakes. In all these cases the mucus has been found slightly alkaline, except that of the digestive tube, which remains acid. This alkaline property is owing to the presence

of a small quantity of soda. These copious secretions of thin mucus often prove critical, in relieving attacks of congestion or slight inflammation.

In more acute inflammation there is excreted in the beginning a very acrid seromucous fluid, which excoriates the lips in coryza, the cheeks in ophthalmia, the anus in diarrhoea, and the internal surface of the thighs in leucorrhœa; this thin acrid mucus is sometimes streaked with blood, as in bronchitis and dysentery. It differs from the mucus of congestion or mild inflammation by coagulating in boiling water and containing albumen; its acidity is due to the presence of alkali (soda); the quantity of albumen is sometimes so considerable that it floats in the thinner part of the fluid in white lumps, differing in no respect from the albumen contained in the serum of the blood, but that there is mucus incorporated with it. At this period of the inflammation there is sometimes an exudation of fibrine as well as of albumen, and this leads to the formation of the false membranes frequently found in the larynx, the trachea, or in some portions of the alimentary canal. As the inflammation advances, the secretion lessens in quantity, and it becomes completely suppressed when the inflammation has reached its height; there is only then exhaled a very small quantity of a thin viscid fluid, frequently more or less tinged with blood.

When the inflammation begins to abate, the secretion returns, becomes very copious, and assumes new characters and properties, having a striking analogy with the favourite hypothesis of *cocoon* of the ancients. In ophthalmia it is effused in considerable quantities on the surface of the conjunctiva under the appearance of a yellow opaque viscid fluid, distinctly globular, and still a little acid; it presents nearly the same characters in coryza. In acute bronchitis the expectoration, which consisted first of a thin mucus mixed with some albumen, now assumes the appearance of opaque, yellow, conglomerated masses, surrounded with some mucus, and constituting well formed sputa, such as were termed by the ancients *well concocted*. In diarrhoea there is a greyish, yellow, viscid fluid, containing small portions of coagulated albumen; in blennorrhagia a profuse secretion of a viscid opaque fluid of a yellow colour, inclining sometimes to green. All these secretions, when analyzed, separate into two principal fluids; one, of a milky colour and transparent, floats on the surface of water, or is suspended in it in small flakes; the other, which is of a greyish yellow, and presents all the characters of genuine pus, sinks to the bottom of the vessel. Puriform mucus floats on the surface of water, if the mucus preponderates; but if the pus be in larger quantity, it sinks to the bottom. In very severe inflammation the secretion consists of very little mucus, but almost entirely of pus, and the viscosity of the expectoration diminishes with the increase of the latter.

In chronic inflammations of mucous membranes, and especially in old catarrhs, if the inflammation is very moderate, the secretion is often purely mucous and not purulent; it sepa-

rates into two parts, one transparent, slightly viscid, and chiefly serous; the other more opaque, greyish, flaky, grumous, and consisting of pure mucus: it is sometimes streaked with black from the secretion of the bronchial glands. If an acute inflammation supervenes on the chronic, the expectoration becomes more thin, abundant, acrid, or frequently purulent, and does not resume its usual qualities until the inflammation abates. These exacerbations of old catarrhs are generally attended with great irritation. Profuse mucous or sero-mucous secretions of long standing must not be supposed always to indicate chronic inflammation, as they sometimes occur spontaneously by a mere increased activity of secretion. When, however, the secretion is both purulent and mucous, it is always a sure sign of the presence of inflammation either acute or chronic: profuse purulo-mucous discharges of this description occur sometimes in coryza, bronchitis, and colliquative diarrhoea, and are attended with considerable debility.

The alterations of the bronchial secretions in pneumonia are also striking and important. In the first stage of inflammation there is expectorated a white viscid frothy fluid, containing a good deal of saliva; it gradually acquires a yellow and then a green tint; its viscosity increases so much that it separates into two parts, the one a thin frothy fluid, the other a thick viscid ropy substance, which sinks and adheres to the vessel. About the third or fourth day the expectoration is often slightly tinged with blood, either uniformly or in streaks, and of a bright red or iron dusky colour; it has generally a saltish taste; the blood is, however, closely incorporated with the sputa, and not free, as in hemoptysis. The expectoration at this stage is found to contain mucus, albumen, and a certain proportion of fibrine, united with some of the colouring matter of the blood; it is the combination of albumen and fibrine with the mucus that renders the expectoration so plastic, adhesive, and ropy.

In the second stage of pneumonia, or that of red hepatization, the expectoration presents the same characters, only that the thinner fluid becomes also tinged with blood, which gives the whole expectoration a dirty pale-red colour; there is, however, a considerable decrease in its quantity. In partial and interlobular pneumonia the expectoration may continue purely catarrhal, or be only very slightly coloured.

In the third stage, or that of the grey hepatization, the secretions being suspended, there is for some time little or no expectoration; but as soon as the inflammation, having reached its height, begins to decrease, the expectoration returns. From being viscid, adhesive, and sanguineous, as described in the second stage, it becomes yellow, opaque, less tenacious, and also less tinged with blood; it sinks in water, and possesses all the characteristics of pus. As the resolution advances, the expectoration gradually becomes less purulent, and assumes again the plastic, viscid, sanguineous appearances of the second stage of inflammation; it then passes from this state to that of pure mu-

cus, until, on the complete restoration of the pulmonary function, it finally disappears.

The transition of the tenacious bloody expectoration into purulent can be very distinctly traced by dissection in the bronchial tubes of an inflamed lung. If the inflammation be arrested in the second stage by active treatment, the expectoration, instead of assuming a purulent character, loses its viscosity, becomes more sanguineous and very frothy: this change is favourable, as it indicates a more free admission of the air into the inflamed pulmonary texture, and an exudation of blood on the surface of the mucous membrane—a kind of bronchial hemorrhage, which tends to relieve the pulmonary congestion and inflammation. It is evident, therefore, that the formation of pus requires that the inflammation should have attained a certain height, and the blood have been submitted to a certain elaboration; this corresponds exactly with the notion of *coction* entertained by the ancients, which, however ridiculed by some, was founded on a correct observation of nature.

In chronic pneumonia the expectoration consists of thin transparent mucous fluid, and of a yellow purulent matter, which sinks to the bottom. In chronic catarrh and bronchitis we have already seen that the expectoration is sometimes purulent, but consists in other instances of mucus, more or less viscid or diluted. Purulent sputæ always sink in water; mucous sputæ sink in water when very thick and viscid, but float on the surface when thin and flaky, and pure pus floats on water when mixed with a large proportion of mucus.

It has thus been seen that in the inflammation of mucous membranes, the component parts of the blood undergo distinct changes, by which all the morbid phenomena can be explained as satisfactorily as in phlegmon. The serous portion of the blood, which has acquired increased coagulability, is exhaled with some of the fibrine, and frequently tinged with the colouring matter; the albumen of the serum, and the fibrine, supply the materials for the secretion of pus; and all these fluids are mixed in various proportions with the natural secretions of the membrane, which have themselves undergone certain changes both in quantity and quality.

The secretions of the skin experience corresponding alterations in inflammation. The skin, when inflamed, secretes at first a serous fluid analogous to the serum of the blood, but containing an increased quantity of albumen, which gives it a gelatinous appearance; as the inflammation advances, a portion of fibrine is added, increasing the tenacity of the secretion, and forming sometimes a plastic membrane. These changes may be observed in the bullæ arising from blisters, sinapisms, burns, &c. When the inflammation has reached its acme, the gelatinous layer becomes more dense and friable, acquiring a yellow opaque colour, and all the properties of pus. In chronic erythematic affections the pus is sometimes greenish, tinged or mixed with pure blood. The secretions of the inflamed sebaceous glands are sometimes incorporated with the sero-albumi-

nous or purulent fluid, giving it a peculiar fetid odour, varying in different parts of the body. It is by the concretion of these various fluids that the scales and crusts of cutaneous diseases are formed, as observed in herpes, tinea, psoriasis, &c. and it is also from the sebaceous matter that these crusts derive their peculiar odour.

The changes which the blood undergoes in inflammation, and its mode of conversion into pus, are the same in all textures; the intimate composition of the pus is also identical in all, presenting only such modifications as necessarily arise from the character and degree of intensity of the inflammation, and from the intermixture with other fluids. As the composition of the pus and its various modifications will be more fully considered in the section *Suppuration*, we shall only remark that its globular appearance, and its being composed chiefly of albumen and fibrine, are striking proofs, in addition to those already advanced, of its being derived immediately from the blood.

The exudation, in the inflamed part, of coagulated blood or lymph, and of other materials more or less concrete, proves sometimes so completely critical, that the inflammation subsides, leaving the swelling behind it. The inflammatory products may then remain in the part for a considerable time without undergoing any change, constituting various forms of induration and infiltration. These swellings may at a later period terminate by absorption or suppuration, or else take on some form of specific and unhealthy inflammation, such as the cancerous, syphilitic, scrofulous, &c. The dispersion of the inflammatory deposits without suppuration is partly accomplished by the impetus of the current of the blood gradually removing the cause of obstruction from the clogged vessels, and partly by interstitial absorption, as already stated in describing the phenomena of resolution.

It is important to remark that, besides the tumefaction resulting from the deposit of *morbid* products, inflammation, when much prolonged or often repeated, causes sometimes an enlargement of parts, by exciting an exuberant action of the nutritive powers, and a consequent excessive nourishment termed *hypertrophy*; there is in this case merely an increased activity of the healthy functions, and a preternatural enlargement of the healthy structure, without the occurrence of any morbid process, or the production of morbid deposits. Hypertrophy is more frequently induced by chronic than by acute inflammation. On the other hand, one of the frequent effects of inflammation, as already stated, is to interrupt the healthy functions of a part; it may cause in this manner a waste of parts from deficient nourishment, and reduce them to a state of *atrophy*; this is more generally a consequence of acute inflammation. These opposite results of inflammation are sometimes observed in parts composed of different structures; an exuberant nourishment of one tissue is generally attended with a deficient nourishment of the other tissues of the same organ. We some-

times see a considerable thickening of the investing membrane of an organ, and a wasting of the substance of the organ itself.

The nutritive powers may not only deviate from the healthy standard by being increased or diminished, but are sometimes also perverted; and this leads to *transformations* of texture. One tissue may thus be changed by a mere aberration of nutrition into a structure corresponding exactly with some of the tissues already in existence in the body, such as bone or cartilage; and these transformations are called *analogous*. But parts that have been long exposed to chronic inflammation frequently acquire a new structure in consequence of a vitiated nutrition, totally different from any in the healthy body; and these transformations are called *non-analogous*. They give origin to a variety of tumours, simple or compound, hard or soft, benign or of a malignant nature. Acute inflammation generally lessens the cohesion of tissues, and often reduces them to a remarkably pulpy state, by a peculiar process termed *softening*. Chronic inflammation, on the other hand, has a greater tendency to cause parts to become indurated. There are many exceptions, however, to these rules. Softening and induration are sometimes combined in the different textures of the same organ; but we must refer to the articles *INDURATION*, *SOFTENING*, *HYPERTROPHY*, *ATROPHY*, for fuller details of these important changes.

When the sensibility and vascular action of a part are so completely destroyed that all vital motion ceases, the dead animal tissues are soon affected with putrefaction, and this constitutes what is termed mortification. When this occurs as the direct effect of inflammation, it is to be attributed either to its excessive violence causing the rupture of a great many vessels and a considerable extravasation of blood, or to the nature of the exciting cause, or to some obstruction of the circulation. We shall not, however, enlarge here upon this and some other effects of inflammation, such as ulceration, effusion, &c. as our only object in this section is to describe those morbid changes which are best calculated to illustrate the theory of inflammation, so as to enable us to define it accurately from all other morbid actions. We must, therefore, refer the reader for further details to the articles *MORTIFICATION*, *ULCERATION*, &c.

Although the preceding changes of structure are frequently the consequence of inflammation, it is necessary to remember that they may occur without any inflammation: the preternatural growth of a part presupposes some increased action of its vessels, but this may take place within the limits of healthy action, and the increase of growth does not at all require that it should be carried to such an extent as to become morbid. It is obvious that atrophy is more likely to be the effect of deficient than of increased action; and both induration and softening are frequently seen to take place under the influence of debility rather than of irritation. A perverted state of the nutritive functions will sufficiently account for all transformations of texture, without the necessity of admitting any

increase of action; when they are attended with inflammation, this is much more generally to be considered as an ultimate effect of the irritation they have excited in the surrounding parts, than as an exciting cause; there is, however, no doubt that a state of long-continued irritation is one of the most powerful predisposing causes of these changes of structure.

It is important also to observe that many of the other common effects of inflammation sometimes occur without any inflammatory action: that increased secretions, effusions, hemorrhages, adhesions, suppuration, ulceration, and mortification may be the result of a state even opposite to inflammation, is a fact fully established by numerous pathological observations. There are numerous examples of large adhesions in the pleura in persons who had never experienced inflammation of the thoracic organs. Ulceration occasionally occurs in the skin and in the mucous membranes of the alimentary canal and of the throat, without any perceptible inflammation, and when the parts, on the contrary, are quite pale: this frequently happens also in scorbutus. Collections of pus are sometimes found in parts which do not exhibit the least trace of inflammation. Cases of this description, however, are of rare occurrence, and may be considered as exceptions to the general rule. The mortification of the extremities arising from ossification of the arteries is an example of its occurrence independently of inflammation; and we have occasionally instances of the same kind in gangrene of the lungs.

After inflammation and its consequences have been completely removed, the vessels of the part frequently remain weak, relaxed, and irritable, and greatly predisposed, therefore, to a return of the inflammatory action.

Besides the local effects resulting from the application of stimulants to a circumscribed part of the living body, of which we have given an account, they sometimes also excite perturbations in all the functions of the animal economy; this is illustrated by the following experiments, first performed by Kaltenbrunner, and which we have repeated. When a stimulant is applied to the web of the foot of a frog, in the course of a few hours all the symptoms of congestion, such as quickened circulation, increased redness, and slight tumefaction, are not only observed in the part first subjected to the irritation, but nearly to an equal extent also in the web of the other extremity. The irritation has, therefore, spread by sympathy to the whole circulating system, producing an increased redness and coagulability in the entire mass of blood, an increased activity and turgescence of all the vessels, analogous to that observed in the original point of irritation. In fact, a species of general congestion has taken place, constituting fever; this sympathetic fever subsides with the local congestion. If a very acrid and poisonous stimulant, such as a solution of muriate of mercury, be used, the following remarkable results occur:—signs of severe pain; great acceleration of the circulation in the webs of both feet; the globules of the blood, instead of a

vivid red, assume a dark brownish colour, and the blood shews a tendency to decomposition; the texture of the webs is tumefied, but rather pale; the skin of the whole body is pallid and covered with a thin mucus; after some time the vessels become less turgid; they contain but a small column of blood and are relaxed, their contractions continuing rapid but feeble. Small ulcers appear on different parts of the body, and the animal finally dies. In this instance we first see a local inflammation followed by sympathetic fever, and next the fever itself becoming the cause of secondary inflammation in various other parts of the body. The essential characters of fever are, therefore, increased quickness of the circulation, alterations in the quality and quantity of the blood, general turgescence of the blood-vessels, and, as aptly remarked by Kaltenbrunner, a species of inflammatory erethism. In secondary fever the local effects of stimulants are propagated to the whole vascular system, whilst primary fever itself may become the exciting cause of local inflammation.

The character of the fever may vary according to the previous state of the constitution, and the activity and nature of the stimulant. If a powerful stimulus be applied to a constitution in which there is a redundancy of rich blood and great activity in all the functions of life, the reaction will be strong, and the fever of a highly inflammatory nature. If, on the contrary, the mass of the blood be deficient in fibrine and red matter, and the vital powers low and little excitable, there will be less tendency to symptomatic fever. It has been observed that the lower animals are less subject to fever than the higher, but sink more rapidly under it. If there be a predominance of the nervous system, a great mobility of fibre and spare habit of body, the fever will be characterized rather by nervous irritability than great vascular action. If the irritating cause be of such a nature as to act chiefly on the nervous system, by first exciting and then depressing it, as is the case with various animal and other poisons, the fever will also assume an essentially nervous character. If a vitiated state of the blood and fluids be combined with an exhausted and irritable nervous power, we shall have the most formidable and pernicious kind of fever, characterized by an alarming combination of nervous and inflammatory symptoms: this is still more likely to occur if the exciting cause itself be of a depressing nature, such as animal and other poisons, the putrid matter of dissection, over-exertion of mind; depressing passions, &c. Finally, the exciting cause may operate on constitutions characterized by a specific morbid diathesis, such as the scrofulous, rheumatic, gouty, cancerous, &c.; in which cases the fever assumes a variety of well-defined modifications: all these varieties of constitutional fever will be more particularly considered in their proper place. (See *Constitutional Symptoms*.)

General inflammatory appearances of the blood.—Besides the various alterations in the composition of the blood that have been described

as occurring in local inflammation, the qualities of the entire mass of the blood are liable also to be affected in certain states of the constitution, which either predispose to, or are consequent upon, local inflammation; there is, it may be said, a general inflammatory condition of all the fluids of the animal economy, and this is especially true with regard to the blood, the inflammatory characters of which we shall proceed to describe.

When blood is drawn from an individual affected with an inflammatory disease sufficiently severe to disturb the constitution, the nature and appearance of the coagulum differ very materially from those of healthy blood; it contains a larger proportion of fibrine than healthy blood, and the fibrine at the top of the coagulum forms a layer of a yellowish white or slightly greenish colour, varying in thickness from less than a line to one or two inches; this layer has received the name of *size*, *buff*, or *buffy coat*; the surface of the coagulum is also frequently contracted, puckered up at the edges, and concave in the centre: the blood is then said to be *cupped*.

According to the researches of Hewson, Dowler,* Gendrin,† and others, the buffy coat consists of pure fibrine, deprived of the colouring matter, and mixed with a certain quantity of serum, which is found to contain much more albumen than the serum of the rest of the blood. There is a great analogy, therefore, both in appearance and in chemical composition, between the buffy coat of the blood, and the coagulable lymph that constitutes dense membranes. Besides the buffed and cupped appearances just described, the coagulum is in general of a greater density than in health, and less easily broken; it is firmly contracted and dry, in consequence of the serum being more completely pressed out of it, and it appears for this reason smaller in proportion to the quantity of serum; it has an ovoid truncated shape, and is frequently found floating in the centre of the vessel on a level with the serum. The cupped appearance, however, and the firmness both of the buffy coat and of the entire coagulum, are usually proportionate to the strength of the patient and severity of the inflammation, and are also greater in the inflammation of certain textures than of others, such as serous membranes, aponeuroses, tendons, ligaments, and other fibrous tissues. But it should be remembered that there is sometimes considerable firmness of the coagulum without any buff or cupping.

When the buffy coat is soft, the coagulum is less cupped, softer and larger, adheres to the bottom of the vessel, and contains more serum; the layer of buff is also thinner, and there is in reality a larger proportion of serum, although this may not be apparent at first, in consequence of its not being so completely separated from the coagulum; the blood is then sometimes described as being *sizey*.

Whenever there is an excess of the serous portion of the blood, the coagulum will be found soft.

The serum of inflammatory blood is also proved, by the researches of Dr. Trail and Gendrin, to be altered in quality, and to contain nearly twice as much albumen as in the healthy state. Gendrin has sometimes observed, especially in cases of chronic and suppurative inflammation, a *mucous layer* either at the bottom of the serum, or suspended in it like a cloud; the buffy coat in these cases was also of a more obscure white, less transparent, and softer.

The following are the appearances presented by the blood under different degrees of inflammation, according to numerous experiments made by Gendrin.*

In cases of very severe inflammation the blood coagulates rapidly. The buffy coat is thick, greatly cupped, firm and elastic; the coagulum has the form of an oval truncated at both extremities; it is dense and elastic (containing little serum), and floats on the surface of the serum, to which it bears the proportion, in point of volume, of one to one and a half, and sometimes two. The serum is viscid, colourless, and a little turbid at the bottom, but contains no colouring matter. In some rare cases of extreme inflammation, the proportion of serum is less than that of coagulum; the buff is very thick and dense, the coagulum adheres to the bottom of the vessel, where it is broader than at the top, having the shape of a truncated cone.

In cases of moderate inflammation the buffy coat is not so thick; there is little or no cupping; the coagulum is firm, cylindrical, and floats in a yellowish serum, equal in quantity to twice the volume of the coagulum; there is also a slight layer of colouring matter at the bottom of the vessel.

In sub-acute inflammation the coagulum may be slightly buffed, but more generally presents on its surface a layer of a bright red colour, and one or two lines in thickness; it is dense, slightly ovoid, and floats in the serum, although it sometimes either adheres to the vessel, or sinks to the bottom. The serum is viscid and limpid, but of a reddish colour at the bottom of the vessel, in consequence of the precipitation of some of the colouring matter; the serum equals in quantity at least twice the volume of the coagulum.

There may occur, of course, many modifications in degree between each of the preceding divisions; but this general outline will be sufficient to guide us in estimating the character of the inflammation, as far as we can depend upon the appearances of the blood.

It is important to notice that the blood may present all the inflammatory appearances just described, without the actual existence of any inflammation. Ratie and Belhomme ascertained by numerous experiments, that the blood of individuals in a state of sanguineous plethora was often buffed and cupped; this circumstance

* On the Products of acute Inflammation, by M. Dowler, Med. Chir. Trans., vol. xii.

† Histoire Anatomique des Inflammations, vol. ii. VOL. II.

* Op. cit. vol. ii. p. 430.

affords an additional proof, if any were wanting, that the general state of the blood may become a primary cause either of inflammatory fever or of local inflammation. The same inflammatory appearances are frequently observed also in pregnancy; the constitution of a pregnant woman bearing the closest analogy to the inflammatory diathesis, for the extraordinary increased activity of the circulation in the uterus borders on inflammation, and the general circulation of the mother is in a state approaching to symptomatic fever. The buffy coat has also been found in individuals who were in the habit of being bled, as a measure of precaution, at certain periods of the year.

The buffy coat and cupped-like form have been observed in the arterial blood during inflammation. Dr. Tweedie has seen it on two occasions; one was a case of inflammation of the chest, in which the temporal artery was opened in consequence of failure to procure blood from the veins; the other was a case of cerebral fever, in which blood was also taken from the temporal artery. Gendrin says that, on the only two occasions in which he opened the temporal artery, he observed a thin layer of buff, slightly coloured, on the surface of the blood.

The presence of the buffy coat may generally be considered as a correct indication either of the actual existence of inflammation, or of a strong predisposition to it; and when the obscurity of the other symptoms leaves any doubt respecting the inflammatory nature of a case, a buffed and cupped appearance of the blood will tend greatly to confirm us in the opinion of the disease being inflammatory. The degree of buffiness is not, however, in proportion to the danger of the inflammation; for, as already stated, in the inflammation of fibrous tissues, the blood is in general more intensely buffed and cupped than in that of vital organs. The absence of the buffy coat is not, on the other hand, to be taken as conclusive evidence of the non-existence of inflammation. We have seen that in sub-acute inflammation the buffed and cupped appearances are often wanting, and that they accompany the inflammation of certain tissues more constantly than that of others. In some inflammations of the mucous membranes, for instance, such as bronchitis, the blood frequently exhibits no buffiness or cupping. In weak or phlegmatic subjects also, whose blood is impoverished and whose constitutions are not very susceptible of sympathetic irritation, an important organ may be affected with dangerous inflammation, although the blood exhibits no indication of such a state of disease, and has, on the contrary, a dark red, jelly-like, and decomposed appearance. This has been observed in cases in which the inflammation has run rapidly to gangrene, or when the fever was of a typhoid character. It has also sometimes occurred in these cases, that when the typhoid symptoms have subsided, and the fever has assumed a more acute character, the blood has then become buffy. Whenever, therefore, there are other well-marked symptoms of inflam-

mation, we are not to attach much weight to the fact of the blood not exhibiting the usual inflammatory appearances.

The immediate cause of the formation of the buffy-coat is obviously the circumstance of the colouring matter of the blood beginning to subside before the coagulation is complete, so that the upper part of the coagulum loses its redness. There have been numerous speculations respecting the *remote* cause of the buffiness, none of which, however, can be considered as satisfactory. Hewson, Dowler, and some others, thought that the fibrine of inflamed blood became lighter; the latter states that he found the fibrine of the buffy coat to contain a larger proportion of serum, which, by diminishing its viscosity, facilitated the precipitation of the red matter. Hunter took an opposite view of the subject, conceiving that the red matter was squeezed out by the firmer coagulation of the fibrine: this is probably in part correct, as we find the coagulum of inflamed blood much firmer than in its healthy state. Hewson and other writers have also affirmed that inflamed blood coagulates more slowly than healthy blood, and that more time is thus allowed for the subsidence of the red particles. This opinion, however, is controverted by Dr. Davy and Gendrin; the latter maintains, as the result of many experiments, that the coagulation of inflamed blood commences sooner, and is completed more quickly than that of healthy blood. That the slow coagulation of the blood is not sufficient to account for the formation of the buffy coat is clearly proved, moreover, by some experiments related by Dr. Stokes, in his *Pathological Observations*. He made twenty-seven experiments, in fifteen of which a buffy coat was formed, and in the remainder it was wanting. No coagulation took place in three of the latter class of cases, in less than from twenty to forty minutes, and in four there was no coagulation for eight minutes; there was, therefore, ample time for the red particles to have separated from the fibrine; while in twelve out of the fifteen, in which there appeared a buffy coat, coagulation took place in five minutes, and was only delayed for fourteen minutes in the three others.

Although the comparatively slower coagulation of inflamed than of healthy blood cannot be admitted as the cause of its buffy appearance, it is nevertheless certain that every circumstance favourable to an *unusually rapid* coagulation of the blood has the effect of preventing altogether the formation of a buffy coat. These circumstances are principally the following: a narrow opening of the vein, so that the blood trickles down slowly in a small stream; being thus exposed to the cooling influence of the air, it coagulates almost instantly on reaching the vessel, so that there is necessarily no time for the separation of any of its constituent parts. We may sometimes account in this manner for the first cup not exhibiting any buffiness, while, if the blood is made to flow afterwards more freely, the buff may form in the second cup, in consequence of

its coagulating more slowly. The formation of the buffy coat may also be prevented or very much lessened by the blood being received in a flat vessel, and especially if cold; for by warming the same vessel so as to delay the coagulation, the buff has made its appearance. It is likewise prevented by letting the blood fall into the vessel from a height of three or four feet, or by keeping the blood for some time in a state of agitation, or by adding a solution of caustic potash.

The formation of the buff is, on the contrary, favoured by making the blood flow from the vein in a full stream, and by receiving it in a deep and narrow vessel. A narrow vessel is also the most favourable to the blood assuming the cupped appearance, which it very seldom does in broad and shallow vessels. Some have advanced that the mere acceleration of the circulation was sufficient to impart to the blood its inflammatory characters; but this is denied by others, and Sir Charles Scudamore says that he has never observed any buff in cases of simple fever, or after violent exercise.*

It is evident, therefore, that although the buffiness and cupped-like form peculiar to inflamed blood may be influenced in a certain degree by the various accidental circumstances just mentioned, these are wholly insufficient to account for this remarkable property, and that it must depend on some other cause with which we are unacquainted. The following remarkable facts would tend, however, to show that this property is immediately connected with some peculiar influence exercised by the vital powers of the system over the mass of the blood. The first cup of blood is often buffy, when the second is much less so, and the last one not at all. Now bleeding is frequently attended with an immediate diminution of the violence of the inflammatory symptoms, even while the blood is flowing; and the rapid change in the appearance of the blood may therefore be justly attributed to the amendment in the state of the patient. If at the end of some hours the inflammatory symptoms increase, and blood be again drawn, it will be found to have re-assumed the buffy appearance. Gendrin has observed on several occasions, that if blood was taken immediately after recovery induced by syncope, it not only had lost its inflammatory character, but that the clot was much softer; and the effect of syncope in rapidly subduing the inflammatory diathesis is well known. We have already stated that the fibrine is more abundant in inflamed than in healthy blood; it has been found, moreover, that the quantity of fibrine varies with the buffy appearance in the different cups, the blood of the first cup containing more fibrine than that of the second, so that the relief afforded by the bleeding is attended also with an immediate change in the proportions of the constituent parts of the blood.

In some diseases of debility in which the blood and other fluids are greatly vitiated, the blood is often extremely deficient in colouring

matter, and the coagulum appears of a dirty yellow or greenish colour. This must not be mistaken for the buffiness of inflammation, from which it will easily be distinguished by the great softness of the coagulum, turbidness of the serum, and general dissolved appearance of the blood.

Uses of inflammation.—Inflammation may generally be considered as a salutary process, instituted by the powers of the constitution, or the *vis medicatrix nature*, for the purpose of preventing, repairing, or removing the consequences of injury and disease; but, like all other salutary efforts of the system, it not unfrequently becomes a source of serious injury, and leads to fatal results, in consequence either of its excessive violence, or of the importance of the part affected.

The salutary effects of inflammation in *preventing* more serious disease is well illustrated by the process of adhesion. When an opening is made in any of the hollow viscera, either by ulceration or violence, the escape of their contents into the surrounding cavities is likely to prove fatal by exciting violent and very extensive inflammation. This, however, is frequently prevented by a slight inflammation set up spontaneously on the outside of the organs, and near the edge of the ulcer or wound; coagulable lymph is effused, and firm adhesions are thus contracted between the opening and the surrounding parts. Adhesive inflammation is often useful in preventing the spreading of disease, as, for instance, of suppuration or ulceration. Both adhesive and ulcerative inflammation assist materially in the removal of foreign substances or collections of matter, which are deeply seated; thus, in cases of hepatic abscess, there are sometimes firm adhesions first contracted between the liver and the large intestine, or the stomach, and then a passage is opened for the pus, by a process of ulceration, into either of these organs, and its escape into the cavity of the abdomen, which would inevitably prove fatal, is thus effectually prevented. A similar process attends the pointing of all abscesses of internal organs towards the parietes of the cavities in which they are contained, and the passage also of foreign substances through important parts of the body.

The advantages of inflammation in *repairing* the effects of injury or disease are illustrated by the re-union of divided parts, and the restoration or reproduction of some which have been partially destroyed, as is the case with bone, skin, cellular membranes, and vessels; there are structures, however, such as the nervous, muscular, and fibrous, which are not susceptible of being reproduced.

When the consequences of injury or disease are to be *removed*, this is effected either by suppuration, ulceration, or increased secretions. When a part of the body has become useless and injurious in consequence of mortification, and when the mortification has a tendency to spread, this is prevented, and the separation of the living from the dead parts effected by a circle of inflammation being excited at their point

* Elliotson's Lectures, Med. Gaz. Dec. 3, 1831.

of contact, which is followed by a gradual process of ulceration, whereby the dead parts are completely cast off.

When, after severe injuries, parts have been so much lacerated and contused that reparation becomes impossible, they are removed by suppurative inflammation. Suppuration is also sometimes of use in the removal of noxious substances and of foreign bodies; this may likewise be effected by increased secretions, or by the effusion of lymph, which afford relief, moreover, by sheathing and protecting the parts from the action of the irritating cause.

Inflammation is sometimes excited spontaneously in various parts of the animal economy, independently of any external cause, for the purpose of getting rid of some noxious or infectious matter which irritates, oppresses, or otherwise disturbs the operations of life; as is exemplified in the exanthemata, in several forms of fever, &c. We see, therefore, that various modes of inflammation are excited, according to the particular object that is to be obtained.

It is evident from the preceding considerations that inflammation is the most frequent of all diseases; it may exist singly, but is often combined with other diseases. When excited for a beneficial purpose, it is always susceptible of assuming a dangerous degree of violence, and this often depends on the state of the constitution. It frequently, however, occurs as a morbid process, not intended to answer any salutary end; and when it affects certain parts, such as vital organs, it is the most dangerous of all diseases.

Congestions.—The morbid phenomena of the second stage of the inflammatory process, which we have described under the name of active congestion, occur in a variety of important diseases which run their course without passing into inflammation, for which, however, they have not unfrequently been mistaken. Some melancholy instances of the injury done by the adoption of a violent course of treatment in congestive affections, in consequence of their having been erroneously considered as inflammatory, have come under our observation. We think it, therefore, desirable to devote a separate section to the consideration of congestive diseases.

The important distinction between inflammation and congestion was clearly defined by the celebrated Laennec in his admirable discourses on the practice of physic delivered at the *Collège de France*, in which he devoted several lectures to the consideration of congestive affections. This distinction has also been kept prominently in view by Andral in his excellent *Pathological Anatomy*, and especially in the section *hyperæmia*, to which we have been indebted for material assistance in this division of our subject.

Between the slightest increase of vascular action and that which constitutes decided inflammation, there are many intermediate degrees. Some of these are so slight and momentary that they do not interrupt the healthy

actions of the part, and may be considered as physiological; such as the flushing of the cheek produced by moral emotions, &c. But in many diseases characterized by disturbance of the functions of nutrition, secretion, or innervation, there is a state of congestion more or less active, which is truly pathological. A congested state of the liver, lungs, or any of the secreting surfaces, may be attended either with a suspension or excessive flow of their secretions. Congestion at the origin of the nerves, in the brain or spinal marrow, is frequently the cause of a variety of nervous affections; it may also be induced by long-continued nervous irritation of the brain itself. A sudden congestion in some organs may be the cause of instantaneous death, as in sanguineous apoplexy and spontaneous hemorrhages. Many of these diseases, although attended with very serious disturbance of the general health and considerable suffering, leave behind them no trace whatever of any change of structure, or else appearances only of an increase of vascularity, quite inadequate to account for the severity of the symptoms. It is evident, therefore, that there is a state of increased activity of the circulation, not amounting to inflammation, which may become an extensive source of disease; and we think this state may be appropriately distinguished from true inflammation by the name of *congestive irritation*. The study of this morbid condition is of considerable importance; for besides constituting of itself an important class of diseases chiefly *functional*, it may lead to inflammation, and lay a foundation for the development of many *organic* diseases; so that it may almost be laid down as an axiom in medicine, that diseases of function always precede diseases of structure. It should be remembered, however, that these morbid actions are closely linked together, passing by imperceptible gradations into each other; and that it is often as difficult to draw the exact line of demarcation between the healthy and pathological species of congestion, as between the latter and inflammation.

Congestive irritation may be more particularly limited to the arteries, the veins, or the lymphatics. Arterial congestion occurs most frequently in children, and venous congestion in old people. The scrofulous diathesis is peculiarly subject to congestive irritation of the vessels and glands of the lymphatic system. The vessels carrying only the colourless or serous portions of the blood, and those destined to the function of secretion, may be affected with congestive irritation as well as the vessels containing red blood, as is seen in sudden attacks of diarrhœa, cholera, &c. Congestions, however, may also occur without previous irritation, depending on debility of the vessels, mechanical obstructions to the circulation, or some alteration in the qualities of the blood. Congestions may, therefore, be divided into active, passive, and serous.

Active congestions.—These may be the effect, as already stated, of a primary irritation either of the nervous or vascular system, or of both con-

jointly: they are characterized by various degrees of increased activity of the circulation; injection and enlargement of the minute vessels; slight tumefaction, and in certain textures, redness, pain, and heat. Or when the congestion is very considerable, there is a languid oppressed circulation from over-distention. Active congestions differ, however, from inflammation, as already stated, by the circumstance of there being no rupture of the vessels or extravasation of blood, no exudation of coagulable lymph, formation of new products, or decided change of structure. Almost every part of the body may be affected with active congestion, but it is of most frequent occurrence in organs of a highly vascular structure, or having numerous direct communications with the heart and large vessels. We shall briefly notice the effects of active congestion in some of the principal organs.

In the brain, which it is obvious must be greatly predisposed to active congestion, it may occasion severe headache, delirium, drowsiness, vertigo, convulsive and other nervous affections; and it may lead to apoplexy, meningitis, or encephalitis: these symptoms are the result either of the stimulus of an excessive quantity of blood, or of its pressure on the cerebral mass and origin of the nerves. The cause of the congestion may not be seated in the brain, but depend on its morbid sympathy with some other organ, or on the general state of the circulation.

The lungs are perhaps more liable than any other organ to be affected with active congestion either of their parenchyma or mucous membrane. This is a frequent source of embarrassed breathing, and of a variety of other symptoms of pulmonic irritation; as, for instance, the dyspnoea attending asthma, chronic suffocative catarrh, and diseases of the heart. There are many other circumstances capable of causing a sudden determination of blood to the lungs; it sometimes happens that while portions of the lung are engaged in chronic inflammation, the rest of the organ is in a state of congestive irritation. Active congestion is one of the frequent causes of hemoptysis.

Congestion of the heart and adjoining large vessels is of frequent occurrence; any obstruction to the circulation from organic disease in the lungs, brain, or large vessels in the neighbourhood of the heart, or any circumstance repelling the blood from the surface and extremities of the body towards the centre, must necessarily cause it to accumulate in the heart; and this may induce either symptoms of quickened and irregular, or slow and oppressed action. Organic disease of the heart is also a frequent consequence of a long-continued state of congestion.

There are many hepatic affections depending on a state of congestion of the liver, not amounting to inflammation. The great vascularity of this organ, and the peculiarities of its vascular system, consisting of a large proportion of veins in which the blood circulates slowly, greatly predispose it to congestion. The majority of hepatic diseases in this climate are

functional, the liver not being so subject to active inflammation as in tropical regions. A congested state of the liver sometimes causes sudden jaundice by obstructing the biliary canals; at others it gives rise to an excessive flow of bile, which is ejected by vomiting or diarrhoea, as in cholera; in some cases it has been followed by ascites, an unusual quantity of blood being thrown into the vessels of the peritoneum, in consequence of the obstruction of the branches of the vena portæ. Some remarkable cases of this description have fallen under our observation, and they have in general yielded readily to an appropriate treatment.

The great extent of the mucous surface of the alimentary canal, its high vascularity, and numerous sources of irritation, sufficiently account for its being frequently the seat of active congestion. The pathology of these viscera, which was for a long period almost entirely overlooked, has been diligently investigated of late years, and its general importance fully established. The influence of a partial congestion and inflammation of this membrane in many diseases, and especially as the proximate cause of continued fevers, has, however, been much overrated. It is particularly with respect to these organs that some pathologists have frequently described appearances as inflammatory, which belonged only to the increased vascularity of active or passive congestion. We have sometimes seen, whilst on the continent, patches of mere redness and injection found in the stomach or intestines, noted down as decided inflammation by disciples of Broussais.

Continued and intermittent fevers, and some of the exanthemata, are generally attended with congestive irritation of several of the internal organs, which sometimes assumes the character of sub-acute, and more rarely of active inflammation. Various degrees of vascular injection and redness are often found in patches in the stomach and intestinal canal of patients who die of fever. In the yellow and some low forms of fever, characterized by violent and irregular determinations of blood, large portions of the mucous membrane present sometimes a uniform dark injection, and the patients in the last stage of these fevers frequently discharge blood by the mouth and anus. The hemorrhagic affections of the alimentary canal, such as hematemesis, melæna, the hemorrhoidal flux, are usually preceded by some degree of congestive irritation, which seldom amounts to inflammation. In melæna the congestion, however, is in general rather passive than active. There is often an unusual quantity of blood forced into the vessels of the alimentary canal in diseases of the heart and liver, giving its mucous coat a highly injected and uniform red appearance: the same may occur when the last struggles of life are violent and much prolonged, but in these cases the congestion is also frequently passive.

The uterus is always in a state of congestion at the approach of the menstrual period. This organ is peculiarly subject to congestive as well as nervous irritation, which sometimes leads to profuse hemorrhage. The morbid

irritations of the uterus exercise a most powerful influence over all the other functions, and especially those of the nervous system. The kidneys are affected with congestive irritation in some cases of hematuria, especially after scarlatina: the only morbid appearance these organs present in diabetes is a dilated and injected state of their bloodvessels. The spleen is frequently found excessively distended with dark blood after continued and intermittent fevers.

We have well characterized instances of active congestion of the skin in a variety of cutaneous diseases. Erythema and erysipelas may be considered as holding a middle station between active congestion and inflammation, presenting the characters of the former when mild, and of the latter when severe. Petechiæ sometimes depend on congestive irritation, though they seem more generally connected with a passive condition of the vessels. The mucous membrane of the nose, mouth, and pharynx is often affected with active congestion: and there is in some individuals an habitual congested state of the pharynx and tonsils that greatly predisposes them to reiterated attacks of cynanche. Sudden congestion of the pharynx occurs also sometimes in hysteria. Several diseases of the bones, such as necrosis, extensive caries, spina ventosa, are occasionally attended with great vascular congestion and profuse hemorrhage. This is also the case with cancer, fungus hæmatodes, erectile, and other tumours.

The preceding general, though imperfect, sketch of some of the principal varieties of active congestion is sufficient to shew that it is a pathological condition of extremely frequent occurrence, and that it includes a number of most important diseases.

Considerable vigour in the powers of life, a great development and activity of the vascular system, with a large proportion of rich blood, will no doubt strongly predispose to active congestions. They, however, frequently occur also in an opposite state of the constitution—one of great general debility. The irritability of both the nervous and vascular systems being considerably increased by weakness, very slight causes are then sufficient to induce severe local congestions. The nervous sympathy existing between the different organs has a remarkable and important influence in the formation of active congestions; the morbid irritation which attracts the blood to one organ is often transferred through the medium of the nervous system to other organs, and disturbs their functions. The occurrence of any considerable change in the circulation of one organ, either in excess or deficiency, frequently tends also to destroy the balance of the circulation in others, constituting in this manner a species of sanguineous sympathy; we accordingly find that a primary congestion is sometimes followed by secondary congestions in other organs, whilst it sometimes has a contrary effect in depriving other organs of their usual quantity of blood. Thus, in congestions of the mucous membrane of the alimentary canal, the skin may be either hot and red, or pale and cold; the brain either violently

congested, or in the opposite condition. The occurrence of these secondary congestions depends of course on the extent of sympathy existing between the several organs, and this accounts for many of the important combinations of symptoms in disease; as, for instance, the cerebral symptoms accompanying active congestions of the stomach and intestinal canal; the occurrence from a similar cause of paroxysms of asthma, or of disordered action of the heart. The morbid irritability of the uterus, either with or without congestion, is a most prolific source of active congestion in either the digestive, the respiratory, the circulating, or the cerebral organs, and gives rise to an endless variety of anomalous and distressing symptoms. A diminution in the usual quantity of blood, and a deficiency in the vitality of one organ, may also become, as before stated, the immediate cause of congestion in others; as, for example, the sudden suppression of the perspiration, or an habitually torpid action of the skin from long-continued exposure to cold and damp; the suppression of the catamenia; of the urinary or alvine excretions; the application of cold and wet to the extremities, &c. If any one organ is in a state of disease, or has previously been so, that organ has the greatest disposition to be affected with either primary or secondary congestion.

When congestion exists in several vital organs at the same time, there is often a combination of most dangerous and alarming symptoms, many of them, however, of a purely nervous character, and leaving no morbid appearances beyond very slight traces of increased vascularity in some of the organs. A secondary congestion has sometimes the effect of aggravating the primary disease, at others it supersedes it; and in some cases there are singular alternations of disease called *metastases*, as is often observed between the brain and the stomach, or the brain and the lungs. These irregular determinations of blood may be traced in a great measure to the influence of the nervous over the vascular system, and especially over the functions of the minute and capillary vessels, for they occur particularly in debilitated subjects, whose nervous system is highly susceptible, and endowed with great mobility: the just balance and harmony of the circulation is easily destroyed under this feeble and unsteady action of the nervous power; points of irritation are excited in various organs from the influence of slight causes, inducing a sudden, unequal, and temporary flow of blood towards these organs, and a consequent train of anomalous symptoms, frequently of a formidable description. It is remarkable how trifling a degree of local irritation and congestion is often sufficient under this state of weakness and irritability to cause violent pain, delirium, convulsions or syncope; this class of patients, moreover, very frequently exaggerate their symptoms. An incautious perseverance in very active remedies in such cases is only calculated to aggravate their condition; and it is often necessary to combine, in their treatment, moderate local depletion with the administration of tonics,

and to depend sometimes altogether on the restoration of the general strength. This important principle did not escape the attention of the great Hunter, for in the treatment of severe ophthalmia, in highly irritable constitutions, he often found bark and a generous diet more successful than depletion and purgatives. It should be observed, however, that long continued disturbance in the nervous action of an organ has a great tendency to induce active congestion, and lay the foundation of organic disease; and this important consideration should never be overlooked in the regulation of the treatment.

The state of the mass of the blood, both as to quantity and quality, is a very frequent cause of active congestion. There is sometimes a greater quantity of blood formed than is required for the purposes of life, and this creates a state of over-distention of the whole vascular system, a sort of general congestion called *plethora*. There is a tendency in some constitutions to make blood more rapidly and in greater quantity than in others; this is favoured by high living and little exertion either of body or mind. There is also a much greater natural development of the vascular system in some individuals, constituting the sanguineous temperament; and the blood is then generally rich in fibrine and red matter. This excess in the quantity and nutritive quality of the blood keeps the solids in a state of permanent excitement highly favourable to the development of active congestion and inflammation. When this excitement is carried to a considerable extent, it ceases to be healthy; every portion of the animal economy is stimulated into inordinate action; the functions both of the nervous and vascular system become generally disordered; the pulse increases in strength and frequency; the temperature of the body is raised; the secretions are variously modified; and all the symptoms of general fever, without any marked local affection, are developed.

This fever from plethora may be mild and soon subside, or else there may be a strong general reaction, giving rise to a variety of alarming symptoms, and sometimes to an apparent prostration of strength from oppression of the powers of life. When this form of fever terminates in death, the only morbid appearance to be discovered is a certain degree of congestion in the minute vessels of the different organs, without any one being more particularly affected than the rest. It has been very justly remarked by Andral, that since, wherever the blood is distributed, derangement of function is found, the first cause of the disease resides indisputably in the blood, the lesion of the solids being only secondary. That cases of fever exactly corresponding with the preceding description do sometimes occur, is a fact as well established by the concurrent testimony of many experienced pathologists, as any in medicine. We have had the opportunity of examining several hundred bodies of persons who have died of fever, and in some of these, although certainly but a small proportion, we have been unable to detect any

morbid appearance worth noticing; the assertion, therefore, of Broussais and his followers that fever is always the effect of a sympathetic irritation of the heart depending on the irritation or inflammation of some other part of the body, and that essential or idiopathic fever has no existence but in the imagination of some pathologists, is directly opposed to general experience. There are few, we believe, who would venture to deny that all the organs are sometimes found perfectly healthy in other acute diseases which have come unexpectedly to a fatal termination; and it may well be asked, why should not the same occur in fever?

A plethoric condition of the system is, however, most generally combined with a great tendency to accumulation of blood and active congestion in the different organs. When the brain is thus affected, a variety of cerebral symptoms, such as have already been described, may manifest themselves, and even a fatal termination be the result, without leaving any other trace of disease than a highly injected state of the vessels. The congestion may more particularly affect the thoracic organs, and occasion distressing symptoms of dyspnoea, cough, palpitations, &c. The digestive and hepatic viscera are very frequently the seat of active congestion from plethora, in which case the digestion may be impaired, the secretions increased or vitiated, and indirect debility induced by the oppressed action of the different organs. It is justly observed by Dr. Barlow, in the article CONGESTION OF BLOOD, that this condition of the system has often been mistaken for common dyspepsia, and a more formidable and permanent disease been excited by the adoption of a tonic course of treatment; whereas, if the mass of the blood be diminished, and the vessels unloaded by means of venesection, by remedies tending to increase the secretions, and by abstinence, the oppressed organs soon recover their free action. The kidneys, uterus, and cutaneous surfaces may be similarly affected, and a natural cure sometimes takes place by spontaneous hemorrhage. The ancients were well acquainted with this state of the system, and were by no means in error when they laid it down as an established pathological principle, that many acute and chronic diseases, especially of the digestive, hepatic, and excretory organs, were to be considered as critical efforts of the constitution tending to rid it of various sources of oppression or irritation, and to re-establish the just balance of the functions. The late Mr. Abernethy has accurately pointed out the great importance of attending to this principle in the treatment of surgical diseases, and he is on this account justly entitled to the merit of having introduced a new era in this department of pathology.

A state of great obesity induces sometimes a form of plethora more dangerous, perhaps, than any other in its consequences, and more difficult to obviate. When a great quantity of fat is deposited under the skin and round important viscera, the small vessels become so com-

pressed that the blood necessarily accumulates in the heart and larger vessels, in which case those organs destitute of fat, such as the lungs and brain, are often oppressed by excessive plethora, and strongly predisposed to active congestion; the action of the heart itself is frequently impeded by the mass of adipose substance surrounding it, and its muscular tissue is even sometimes partly converted into fat: this condition of the system is generally characterized by an extremely embarrassed, slow, and irregular circulation, and great disorder in the functions of the brain, lungs, and heart; in one instance we observed the pulse frequently so low as 28 in a minute, and it never rose to 40.

There may be an habitual excess of blood in one organ, a state of local plethora, whilst the other parts of the body have even less than their natural quantity. This may be the effect of natural conformation. When the thorax is narrow or deformed, the lungs are compressed, and the circulation through them is so impeded that a slight acceleration of the action of the heart will be sufficient to cause an accumulation of blood in their texture. The same may occur in the brain when the head is small in proportion to the size of the trunk, and especially of the thorax. Large men with a small head and short neck often suffer severely from cephalic affections, especially when the heart was large and its action naturally vigorous; on the other hand a very large head and contracted chest may be attended with the very same result, especially in children: in fact any great disproportion in the natural development of different parts of the body, must necessarily predispose to unequal distributions of blood, and this is one source of those peculiarities of constitution termed idiosyncrasies.

Plethora may exist more exclusively either in the veins or arteries; and this difference is in a great measure connected with the period of life. The arterial system being most developed and in greater activity in childhood and youth, active arterial congestion is most common at these ages. As the rigidity of the solids augments with age, the arteries in particular acquire a greater degree of density, and a great number of the minute arteries become obliterated; a larger quantity of blood is consequently thrown into the veins, whose coats offer less resistance than those of the arteries; and the venous system becomes in this manner gradually more distended with blood towards the decline of life, and more liable to be the seat of congestion.* The different periods of life are characterised also by a greater tendency to plethora and active congestion in certain organs than in others; thus, in childhood and youth the brain and thoracic viscera are principally affected, the abdominal viscera in adults, and the brain and abdominal viscera in old age.

Local plethora may be the result of habits

of life and modes of employment. Intense study creates habitual plethora in the brain; occupations requiring a low position of the head and great straining of the sight produce a similar effect. The people employed in Italy in the manufacture of mosaics suffer greatly on this account from congestive and inflammatory affections of the brain and eyes; and the same is observed in a variety of other trades. The seasons and climates exercise a considerable influence over the distribution of the blood. Heat stimulates the activity of the circulation, and creates a tendency to plethora in the skin and superficial parts of the body during spring and summer, as is shown by the prevalence of the exanthemata and other cutaneous affections: this is likewise the case in tropical climates, where some cutaneous affections assume a highly inveterate character. Excessive heat is known also to create a strong predisposition to hepatic congestions and disordered biliary secretions. The application of cold to the surface lowers the activity of the circulation, and repels the blood towards the centre; and hence the great tendency to congestions in the lungs, brain, and mucous surface of the alimentary canal, during winter and in cold climates. The sudden exposure to intense cold has often been instantaneously followed by an attack of apoplexy: the influence of variations of temperature is greatly increased by their occurring suddenly. These changes in the circulation are not the effect merely of the heat of the atmosphere, but also of the different degrees of pressure it exercises on the body according to the variations in its density. Thus, a condensed, pure, and cold atmosphere adds by its pressure to the power of the solids to resist the impulse and distension of the fluids; and the quantity of blood on the surface of the body being thereby lessened, a certain degree of *internal* plethora is the result: whilst in a heated, rarefied, damp, and impure atmosphere, the vessels of the surface being subjected to less pressure, are more relaxed, admit a larger quantity of fluids, and there is a consequent tendency to *external* plethora.

Some ancient pathologists conceived that there were certain conditions of the body independent of the effect of heat and cold, which give rise to alternate states of condensation and rarefaction of the fluids, and which they referred to some particular influence of the nervous system. They explained in this way various sudden congestions whose occurrence could not be traced to any irritation or mechanical cause; they accounted in the same manner for the great extrication of gaseous fluids observed in some nervous diseases, such as hysteria. The motions of the fluids, and their degrees of rarefaction and density, have been supposed by some modern pathologists to be partly regulated by electricity; but these speculations, however interesting, do not yet appear to rest on sufficient evidence to be applied to practical purposes.*

* See the researches of Dr. Reuss of Moscow, published some years ago; the more recent experiments, also, of Dutrochet in France, and Faust and

The last of the causes of local plethora to which we shall allude is of a mechanical nature,—that arising from tight bandages habitually worn over different parts of the body. Every medical man must have had numerous opportunities of witnessing the highly injurious consequences of this pernicious practice, especially in women; they are too obvious to require further illustration.

The introduction into the animal economy of a contagious virus or of any other deleterious principle, such as putrid miasmata, &c. has generally the effect of exciting congestions more or less active in several organs at the same time, as is observed in a number of infectious diseases, such as measles and scarlatina, typhoid and malignant fevers; or after the administration of poisons. These deleterious principles vitiate the qualities of the blood, disturb the whole nervous system by either irritating or depressing it, and thus create active congestions in the brain and alimentary canal.

One of the frequent terminations of congestive irritation of the bloodvessels is hemorrhage, either within the texture of the part affected, or on its surface. When there are no means of escape for the blood, the consequences are often extremely dangerous; as in apoplexy, and likewise in hemoptysis, when the blood is only partially expectorated, and a portion retained within the pulmonary texture. Where, however, the blood can issue freely, the hemorrhage frequently relieves the congestion, as in epistaxis, hematemesis, menorrhagia, &c. This timely hemorrhage often prevents the congestion from passing into inflammation; whilst the repression of the hemorrhage, whether spontaneously or by artificial means, has been sometimes immediately followed by formidable symptoms of inflammation. Hemoptysis has in this way been converted into pneumonia; hematemesis into gastritis; menorrhagia into metritis. The hemorrhage may also prove hurtful by causing an excessive loss of blood, either in one or successive attacks; there is a great tendency to hemorrhagic action in certain constitutions, depending most probably on some condition of the bloodvessels leading to congestive irritation; other constitutions being more predisposed to serous effusions. It should be observed, however, that hemorrhage may occur without any previous congestion of the bloodvessels, either active or passive, the parts after death not presenting the slightest morbid appearance; this must be owing to some modification in the texture of the parietes of the vessels, or to some peculiarity in the qualities of the blood; as, for instance, when reduced to a thin watery state, so that it escapes from the vessels as fast as it arrives. This species of hemorrhage is observed in scorbutus and in the hematuria of old age.

Inflammation is one of the most natural and important consequences of congestive irritation.

The development of many formidable diseases may be prevented if the congestive stage of the inflammatory process can be removed by the timely application of appropriate remedies. Active congestions are sometimes only temporary, and quickly subside: when of long duration, they frequently occasion various alterations in the nutrition and secretions of the part, which they either increase, diminish, or vitiate. They sometimes assume an intermittent and periodical character, as in some forms of cephalalgia, dyspnoea, &c.

Passive congestions.—It has been already stated that congestions are frequently formed without any previous irritation or increased activity of the circulation, and that they may be the effect of a relaxed state and deficient activity of the vessels, of a vitiated condition of the blood, or of some mechanical obstruction to its course: in these cases the congestion is termed *passive*. Passive congestion is characterized by various degrees of redness and sometimes tumefaction, but is distinguished from active congestion by the absence of pain and heat.

The accumulation of blood in the passive congestion sometimes becomes a source of irritation, and the congestion then assumes an active character. On the other hand, a congestion, which was at first active, may after some time become passive. There are, therefore, two forms of passive congestion, the one *primary*, and the other *secondary*.

The principal causes of passive congestion, viz. relaxation of the small vessels, languor of the general circulation, and a thin vitiated state of the blood, are combined in the scorbutic constitution; there is consequently a remarkable tendency in scorbutus to passive congestions and extravasations of blood in all vascular textures. In cases of general debility of the powers of life, and deficient energy of the capillary system, the blood has the greatest tendency to accumulate in those portions of the vascular system the most remote from the propelling influence of the heart, and in which the circulation is chiefly carried on by the contractility of the extreme vessels; and this is still more likely to occur where the blood in its passage from the capillaries into the veins has to overcome the force of gravitation. The lower extremities of old people are sometimes affected, owing to the operation of these causes, with spots presenting an injected, dark-red, marbled appearance, sometimes varicose or in a state of echymosis.* In some cases there is a complete stoppage of the circulation, stagnation and coagulation of the blood; the vitality of the part is destroyed; it becomes cold and insensible; assumes a dark livid colour; and a form of gangrene frequently supervenes, called the *gangrena senilis*. A similar affection is of frequent occurrence in certain forms of fever, and other diseases attended with great nervous debility and a vitiated state of the blood; the application of any slight irritation to the skin, especially in the dependent parts of the body on

Mitchell in America, on the endosmosis and exosmosis of fluids and gases.

* Andral, op. cit. vol. i. p. 50.

which the patient lies, such as the back, sacrum, and nates, is followed by the appearance of red patches of congestion; these, at first acute, soon become passive, and assume a gangrenous appearance.

All the internal organs are subject to passive congestion. When death is attended with violent struggles, as is the case from the convulsions of tetanus, of asphyxia, by strangulation, or from the effects of certain poisons, many of the internal organs, and particularly the brain, are found loaded with blood, and more or less injected. When after protracted diseases death occurs very gradually, the lungs are sometimes found gorged with blood and serum, although there was no previous symptom of pulmonic affection. These changes occur more particularly in the posterior portion of the organ, when the patient lies constantly on the back. They can only be referred to debility of the capillaries and passive congestion, as they were not preceded by irritation. After the inflammation has been subdued in acute pneumonia, and convalescence is established, there remains in some cases a certain degree of dyspnoea and crepitating rhoncus, although the thorax has recovered its natural sound on percussion, and these symptoms resist the continuation of antiphlogistic remedies, whilst they yield readily to the employment of tonics. The congestion of the bronchial membrane in chronic catarrh frequently requires a tonic plan of treatment, and it may be fairly concluded in both these cases that the vessels are in a relaxed and passive condition.

There is a great predisposition to passive congestion in the mucous membrane of the alimentary canal. This is not surprising when we consider how largely it is supplied with bloodvessels, their subdivision into numerous arches supported only by a loose membrane, and, above all, the peculiarities of its venous circulation; for the venous blood of the alimentary canal being distributed to the liver by veins deprived of valves, the slightest obstruction to the circulation of that organ, which is naturally slow, must have the effect of retarding the return of blood from the intestines, and creating an accumulation in their venous system. This accounts for the frequency of hemorrhoidal affections, diarrhoea, and dysentery, in chronic affections of the liver. In fevers of a low, nervous, and malignant type, the mucous membrane of the intestines, and chiefly of the colon, is sometimes found of a uniform dark-red colour, turgid and soft, in consequence of an intense venous injection of a passive character, the black pitchy secretions of the membrane resembling decomposed venous blood.* In a case of this description the mesentery was covered with large dark-red blotches, giving it the appearance of a leopard's skin, and arising from a state of intense injection of the mesenteric veins with extravasation of blood, the congestion having fallen on

the mesentery instead of the coats of the intestines. The mucous membrane presents frequently similar appearances in melæna; and in a case of recent occurrence we found it impossible to discover the least difference between the black sanguineous fluid contained in the intestines, and the blood taken from the vena portæ.

Mechanical compression or obliteration of any portion of the venous system is necessarily followed by passive congestion in all the parts whose blood is returned to the heart by the obstructed vessels. When this obstruction occurs either in the lungs or heart, it produces passive congestion in all the organs of the body. This is particularly well exemplified in asphyxia, in which the face becomes livid and swollen, the lips purple, the tongue tumid, the eyes red and staring, and the whole surface of the body injected with dark blood. The lungs, right cavities of the heart, and entire venous system are found distended with venous blood, whilst the left cavities of the heart are nearly empty; the mucous membranes of the lungs and alimentary canal are also deeply injected. When the obstruction in the pulmonary circulation takes place gradually, as in pulmonary consumption, the same general congestion is not observed, because the absolute quantity of blood in the whole system is diminished by long-continued imperfect sanguification, deficient nutrition, and increased excretions. A nearly similar state of general passive congestion is sometimes produced by diseases of the heart, whether congenital, as in the morbus cœruleus, or acquired.

Serous congestions.—The order of vessels which convey only the colourless or serous portion of the blood, are liable also, as before stated, to be affected with congestive irritation. These vessels exhale in health a sero-albuminous fluid or vapour, which constantly lubricates the areolæ of the cellular tissue, the cavities lined with serous membranes, the mucous and cutaneous surfaces, and, in fact, every part of the body. It can be satisfactorily shewn, by a variety of experiments, that this fluid is supplied by the serum of the blood. If, for instance, a solution of prussiate of potash be injected into the veins, it can be immediately detected in the fluid of the serous membranes by means of sulphate of iron.* Serous and sanguineous congestions are not unfrequently combined; the former may, like the latter, occur without previous irritation, and be passive.

Congestive irritation of the colourless vessels is generally followed by an increased exhalation of serous fluid, which is either retained in the areolæ of tissues and closed cavities of membranes, constituting different forms of effusion, or, when poured out on the mucous and cutaneous surfaces, is carried off in the form of increased excretions.

Those portions of the cellular tissue the texture of which is loose and the position dependent, are the most frequently the seat of serous effusions. The dense cellular tissue

* Dr. Armstrong made these congestions the foundation of one of his divisions of fever, which he termed *congestive*.

* Andral, op. cit. vol. i. p. 379.

lining mucous membranes is not, however, exempt from serous infiltration; the membrane is then raised, loose, and flaccid, as is well exemplified in that fatal disease, œdema of the glottis. When serous effusions occur in the membranes investing vital organs, they often give origin to various formidable and fatal diseases. The investigation of their causes is, therefore, deserving of some consideration. These causes may be divided into increased action of the vessels, debility of the vessels, alterations in the qualities of the blood, and mechanical obstructions to its circulation.

Serous effusions may take place from irritation and increased activity of the secreting vessels, without the cellular tissue or serous membrane undergoing any alteration of texture, or presenting even the slightest appearance of sanguineous congestion. If the irritation be slight, the effused fluid corresponds exactly in its composition with the serum of the blood, consisting of a large proportion of water (900 in 1000 parts), a small quantity of albumen (80 in 1000), and the remainder made up of soda, various salts, and an animal matter analogous to mucus.* Under certain circumstances not connected with irritation the effusion contains also a substance called extracto-mucus, either uniformly combined and giving it a slight turbid appearance, or floating in the midst of the fluid in small filaments or flocculi. As, however, the irritation increases, the proportion of albumen becomes considerably greater, and this substance is therefore a good test of the violence of the irritation. When the congestive irritation reaches the point of true inflammation, the disease is characterized by other morbid changes; there is an exudation of coagulable lymph and pus, which, being mixed with the serous fluid, gives it a turbid appearance; the surface of the membrane itself is lined with layers of lymph; its bloodvessels and those of the sub-serous cellular tissue are deeply injected, and blood is sometimes extravasated by their rupture. The absence, however, of any trace of vascular injection in a serous membrane, after effusion has taken place, must not always be considered as a sure proof that it never existed; for there may have been considerable sanguineous congestion in the first period of the disease, which has disappeared after the turgidity of the vessels has been relieved by the exhalation of the distending fluid. We accordingly often observe the symptoms of local and general irritation in acute affections of the cellular tissue and serous membranes, completely subside the moment the effusion has taken place; and we may frequently predict an accession of effusion by the return of these symptoms. It may, therefore, be received as a general rule that a state of congestive irritation, both of the sanguineous and serous vessels, especially when long-continued, is more favourable to acute dropsical effusions than active inflammation; that active inflammation is attended with a greater disposition to the formation of adhesions and false membranes, or to the exudation

of pus and blood, than to copious serous effusions, the function of secretion being rather suspended than accelerated during the inflammatory process. The fever and other constitutional symptoms which precede effusions into the cavities of the head, chest, and abdomen, are accordingly, in the majority of cases, rather of a sub-acute than highly inflammatory character; and it is extremely important to keep this circumstance in mind, as the mild and insidious nature of the symptoms has frequently concealed the real danger of the disease. Serous effusions take place also, no doubt, in the course of severe attacks of inflammation; but effusion is then almost always combined with suppuration and the formation of pseudo-membranes, and it generally occurs when the inflammatory action is on the decline. We have examples of this in pleurisy and peritonitis.

In recent cases the texture of the serous membranes is generally unaltered; but when serous congestion has been of long standing or frequent recurrence, the membrane becomes thickened and of an opaque white, in consequence of the infiltration of the serous fluid between its layers. A similar infiltration takes place into the subjacent cellular tissue, which on this account adheres to the membrane when raised, and increases its thickness; this happens more especially where the sub-serous cellular tissue is loose and abundant, as, for instance, between the arachnoid and pia mater. The free surface of the membrane loses also its smoothness and polish, becoming rough and granulated. In some severe and very protracted cases, the membrane is thickened and even cartilaginous, in consequence of vitiated nutrition. The serous fluid may be either colourless or of a green, yellow, or reddish tint, owing to the presence of a portion of the colouring matter of the blood; it is sometimes mixed with a yellow colouring matter analogous to that of the bile, and has in some cases been found to contain uric acid.

The effusion may be occasioned by a primary irritation of the tissue in which it is formed, or a secondary irritation propagated from a neighbouring part.* Hydrocephalus is in most cases to be attributed to irritation in the brain; ascites is sometimes consecutive to peritonitis; erysipelas, phlegmon, and all extensive and deep-seated inflammations, are attended with œdema of the adjacent cellular tissue. Effusions depending on congestive irritation are characterized by local and constitutional symptoms more or less acute; when they occur in the sub-cutaneous cellular membrane, as in œdema and anasarca, there is swelling and some degree of heat, pain, and tension; this corresponds with the diffuse inflammation described by the late Dr. Duncan. When the effusion takes place within any of the splanchnic cavities, or in the texture of important organs, there are a variety of local symptoms more or less severe according to the impediment occasioned in the functions of the organ. The constitutional symptoms vary con-

* Andral, op. cit. vol. i. p. 389.

* Andral, op. cit. vol. i. p. 393.

siderably, being sometimes violent, at others mild, obscure, and insidious ; this depends very much on the suddenness of the affection, as well as on idiosyncrasy, and other circumstances. A slight degree of congestion and effusion occurring suddenly may give rise to very violent symptoms and prove rapidly fatal ; whilst a higher degree of congestion, and the effusion of a larger quantity of fluid, if it only take place gradually, is sometimes attended with comparatively little inconvenience, there being time for the parts to accommodate themselves to the distention occasioned by the fluid.

The following enumeration of the diseases in which effusion occurs as a consequence of congestive irritation of the serous vessels, will shew the importance of attending to this species of diseased action. It affects both sides of the arachnoid, the pia mater, the lining membrane of the ventricles of the brain, and the medulla spinalis, in arachnitis, hydrocephalus, and hydro-rachitis ; the pleura in pleurisy and hydrothorax ; the pericardium in pericarditis and hydrops pericardii ; the peritoneum in ascites ; the ovaries in hydrops ovarii ; the tunica vaginalis in hydrocele ; the joints and surrounding parts in hydrops articulo-rum, and also the bursæ mucosæ of tendons ; the cellular tissue in œdema and anasarca ; the globe of the eye in hydrops oculi. The parenchyma of several organs may also be the seat of serous congestion and effusion ; the white softening of the brain seems to depend on a species of serous infiltration ; there is a serous congestion of a sub-acute character called œdema of the lungs, which is in general very obscure and intractable, and a frequent, though unheeded, cause of anasarcaous swellings in different parts of the body.

Serous congestion and effusion depend sometimes, as already stated, on debility of the vessels without previous irritation, being what is termed *passive*. In order to give a connected view of the pathology of these affections, we shall offer a few observations on this and some other causes of serous congestion, although not immediately connected with inflammation. When the powers of the constitution have been considerably reduced after protracted diseases, excessive evacuations of blood, or in old age, especially in temperaments naturally leucophlegmatic, serous effusions sometimes occur, to all appearance, from mere debility ; the lower extremities, where the blood has to overcome the greatest degree of gravitation, are most commonly first affected. Effusions from mere vascular debility are, however, by no means so frequent as was formerly imagined. It more generally happens that there is combined with debility some other cause, such as alterations in the quantity or qualities of the blood, or obstruction to its circulation.

Since the fact of absorption being actively carried on by the veins as well as the absorbents has been fully established by the experiments of Majendie, nothing can be more obvious than that the distention of the venous system by an excess of blood must have a special

influence in the production of serous congestions and effusion, by retarding the current of the blood, causing an accumulation in the minute vessels, and lessening the activity of absorption. There are cases of œdema and anasarca which can be attributed to no other cause than extreme plethora ; a remarkable one, which terminated fatally, is related by Andral. That effusion may occur from this cause is clearly proved by the fact of our being able to produce it at will by injecting into the veins a large quantity of water, so as to create a state of artificial plethora. That the absorption of the veins is greatly accelerated when in a condition opposite to that of plethora is also satisfactorily proved ; for if in the same animal we remove the plethora by abstracting blood from the veins, the serous effusions soon disappear : this explains the good effects that follow venesection in acute dropsical affections.

A diminution in the proportion of fibrine and red matter, and a corresponding increase in that of the serosity of the blood, greatly favours serous congestions and effusions : this state of the blood is induced by copious and repeated venesections, which are sometimes followed by dropsical effusions. The long-continued use of a poor and watery diet produces similar results, although the mass of the blood may be diminished in quantity. The coagulating property of the blood is destroyed also by some poisons, especially those of reptiles ; its fluidity is thus increased, and it assumes a decomposed appearance ; the unhealthy malignant inflammation excited by these poisons is accordingly combined with serous infiltrations.

Any obstruction to the venous circulation has a tendency, for the reasons already stated, to induce sanguineous congestions and serous effusions. The obliteration of the principal veins of a limb from inflammation, the pressure of a tumour, or other causes, is generally followed by œdema of the limb below the obstruction. The obliteration of the inferior vena cava causes dropsy of the lower extremities : obstacles to the circulation of the vena portæ, arising from diseases of the liver, are among the most frequent causes of ascites. Several diseases of the kidneys, which have been well described by Bright, Christison, and Gregory, produce a similar effect. When the cause of obstruction occupies the central organs of circulation, as in diseases of the heart and lungs, the dropsical effusions affect every part of the body.

Impediments to the circulation in the lymphatic vessels, which may be considered as a species of veins, are sometimes followed by serous effusions in consequence of a diminished absorption ; this is exemplified in *tabes mesenterica* and in obliterations of the thoracic duct. In some cases of chronic serous effusions Dr. Hodgkin has found the lymphatic glands enlarged and indurated without any evident change of structure, but in a state rather analogous to hypertrophy.

Besides the primary causes of serous congestion and effusion that have been enumerated, there are various secondary causes, amongst which may be noticed the suppression

of secretions, and especially that of the skin and bronchial membrane. Dropsical affections are very common in low and damp situations, which is chiefly to be attributed to the action of a moist atmosphere in lessening cutaneous and pulmonary perspiration. Copious serous effusions disappear sometimes with surprising rapidity; the fluid is in some cases transferred to another part, giving rise to a new train of symptoms; it is frequently, however, carried off by copious excretions. But there are instances of the general health being re-established without any such evacuations.

When the *mucous* and *cutaneous* surfaces are affected with congestive irritation of their serous vessels, it generally induces profuse serous excretions. These surfaces secrete two kinds of fluid, one in the form of a vapour or thin serosity exhaled by the serous vessels, such as the cutaneous and pulmonary perspiration and the watery evacuations from the bowels; the other consisting of the mucus and other secretions supplied by the mucous and sebaceous follicular glands. Very large quantities of these various secretions proceed sometimes from the skin and mucous membranes, without any morbid change in the structure of these parts, or such slight deviations only from their healthy appearance as are in no way proportionate to the severity of the symptoms. These profuse discharges can only therefore be referred to a degree of congestive irritation not amounting to inflammation. If, however, the secretions be checked, either by astringent remedies or spontaneously, the congestive irritation may be converted into active inflammation; and in this manner dysentery and enteritis have sometimes supervened on an attack of diarrhœa.* These profuse evacuations, when occurring in mucous membranes, were called by the ancients *phlegmorrhagiæ*, *phlegmatorrhagiæ*, or *fluxes*. Pyrosis, and some forms of coryza and pulmonary catarrh, have been classed by several nosologists among the *phlegmorrhagiæ*. At the invasion of coryza and pulmonary catarrh there is sometimes a very copious discharge of a watery fluid, either from the nose or by expectoration. The pituitary membrane is tumefied, but without increased redness, and the entire nose sometimes swollen. The quantity of serous fluid proceeding in some diseases from the mucous membrane of the stomach and bowels is enormous; it has amounted to several quarts thrown up from the stomach in some cases of pyrosis, and much larger quantities have been discharged by stool from the bowels in attacks of cholera and colliquative diarrhœa. These profuse excretions generally induce symptoms of as great prostration of strength as from excessive loss of blood; the skin becomes cold and clammy; all other secretions are suspended; the rapid sinking of the strength brings on paroxysms of syncope and convulsions; the blood also assumes a dark red colour, being deprived of its serum. These serous fluxes have sometimes supervened

on the sudden disappearance of dropsy either of the abdominal or thoracic cavity, and have in this way proved critical; they may occur also at the termination of febrile and inflammatory diseases, whose resolution they seem to favour.

The cutaneous perspiration is exhaled in health under the form of an imperceptible vapour. But in many diseases there is a state of congestive irritation of the skin, either primary or sympathetic, characterized by a morbid heat, and the excretion of a profuse serous fluid constituting sweat. These perspirations may likewise be critical in a variety of inflammatory and febrile diseases; in the *morbus sudatorius* they constituted the prominent symptom. They are sometimes passive, being then cold and clammy, as at the approach of death. A remarkable alternation of action is observed in some cases between the skin and mucous surface of the alimentary canal, the suppression of a profuse sweat being followed by diarrhœa, and *vice versâ*. The diarrhœa which attacks the crews of whalers on entering the regions of ice is of this nature. The skin is generally dry and rough in chronic gastritis. In pulmonary phthisis, and other organic affections of the lungs in which the pulmonary perspiration is diminished, there is generally an increase of the cutaneous perspiration, which may be considered as its substitute. The qualities of the perspiratory fluid are modified in several diseases, as is manifest by peculiarities in its odour and flavour, and by the action of chemical tests.

All *glandular* structures, such as the follicles of the skin and mucous membranes, the salivary glands, liver, kidneys, &c. may be affected with congestive irritation of their secreting vessels leading to increased excretions, without any change of structure or appearance even of vascular injection. In all catarrhal affections there is an increased secretion of mucus from the different mucous surfaces; this, no doubt, is sometimes the effect of inflammatory action; but in numerous cases there is merely a congested state of the serous vessels, and not the least appearance of increased action of the bloodvessels, as is clearly demonstrated by numerous post-mortem examinations. Nothing, therefore, can be more erroneous than the opinion of some modern pathologists, that all catarrhal affections are to be referred to inflammation. Andral very justly observes "that it would be a great error to suppose that the fever which accompanies certain acute mucous fluxes is an infallible proof of their inflammatory nature; for the simple fact of an organ being deranged in its nutrition, secretion, or innervation is sufficient to generate fever, no matter whether that derangement be attended with the augmentation, diminution, or perversion of the vital powers of the organ: the bare circumstance of a part of the living body being in a state of suffering, whatever the nature of that suffering be, is sufficient to light up the various sympathies which constitute *fever*. The existence of fever does not, therefore, necessarily imply the idea of stimulus or of excessive action; and, consequently, the object of the

* Andral, op. cit. vol. i. p. 412.

practitioner should not, in every case of fever, be to combat this stimulus; but in some cases it should be to relieve a derangement, either circumscribed and purely local, or affecting generally the blood itself, or the centres of the nervous system." This view of the subject is the most consistent, certainly, with sound reasoning and general experience. It is, moreover, now generally admitted that many of these catarrhal affections, when the period of irritation that attends their invasion has subsided, are aggravated by perseverance in an antiphlogistic plan of treatment, and are speedily relieved by tonic remedies and a nourishing diet. This is particularly evident in chronic pulmonary catarrh and in mucous diarrhoea, to which complaints persons of a relaxed phlegmatic temperament, and much exposed to wet and cold, are particularly predisposed. The secretions of the lachrymal and salivary glands, of the liver and kidneys, may likewise be considerably increased in consequence of congestive irritation of their secreting vessels.

All the affections that have been described as depending on congestive irritation of the sanguiferous or serous vessels, may assume a continued, intermittent, sporadic, or endemic form. The various secretions are in general considerably under the influence of the nervous system, and may be suddenly increased or diminished by strong mental emotions; we need only mention, in proof of this, the well-known effects of fear on the secretions of the bowels and kidneys.

It is evident, from what has been stated in this section, that the morbid condition of the vessels which we have termed *congestive irritation*, includes a great variety of diseases, some of a formidable character, and the exact nature of which has not always been clearly understood. Many of these diseases originate in a high state of congestive irritation closely allied to inflammation; the danger, however, is not always in proportion to the degree of irritation, for we have seen that some diseases characterized by only slight congestive irritation, may in certain constitutions lead to a fatal result, by inducing effusions round vital organs, or exhaustion of the nervous power from hemorrhages and excessive excretions; and that the danger in these cases is so much the greater, that their symptoms are often obscure and insidious. It has also been shewn that when, in consequence of the influence of morbid sympathies, congestive irritation has been excited in several vital organs at the same time, the simultaneous disturbance of their functions, and consequent unequal distribution of the circulating fluids, may give rise to the most formidable symptoms, and prove as certainly fatal as the destruction by inflammation of any vital organ. We have seen, also, that with regard to the treatment of congestive diseases, the practitioner must be on his guard lest the obscure and often insidious character of the symptoms should deceive him respecting the true nature of the disease; that these affections being all more or less allied to inflamma-

tion, generally require an antiphlogistic plan of treatment; that this, however, will sometimes require to be carefully modified, and is likely to prove injurious if carried beyond a certain point, as congestive diseases are often induced and aggravated by a state of general debility.

Morbid appearances of inflammation.—There are few things in the study of pathology more difficult and of greater importance than to define accurately what are the appearances in the dead body by which the different morbid affections of the vascular system, from the state of slightest injection to that of high inflammation, can be distinguished from each other. Accuracy of knowledge on this subject is evidently highly desirable, as our views of the nature of disease can be derived only from the combined evidence afforded by the symptoms observed during life, and the deviations from healthy structure found after death. Before, however, entering upon the consideration of this important part of our subject, it is necessary to premise that a variety of morbid changes of structure sometimes take place, both at the moment of death and at a certain period after, bearing a close analogy to those induced by disease: a knowledge of these changes is of the first importance to prevent their being erroneously attributed to disease.

In speaking of the functions of the minute vessels, we stated that their contractility survived for some time the action of the heart; that in consequence of this they continued to propel the blood into the capillaries and small veins in which it necessarily accumulated, while the larger arteries, not receiving any fresh supply of blood, remained empty. This sufficiently accounts for the circumstance of all delicate vascular textures, the surfaces of mucous and villous membranes; the pulp of the brain, texture of the lungs, &c. often presenting an unusually red and injected appearance in the bodies of persons who die with much blood in their system; these congestions bear a strong resemblance to the passive congestions that are formed during life. They vary according to the manner in which the circulation has been first interrupted, whether in one or both sides of the heart, or in the vessels of one particular organ. The different parts of the body may, however, assume also various degrees of redness and injection after death, which it would be a serious mistake to attribute to the effects of disease. The formation of these congestions can easily be proved by experiment; for if the colour and degree of injection of different organs be noted immediately after death, and the same organs be examined again at different successive periods, parts naturally white will be observed to become red, vessels and patches of ecchymosis become apparent where none could previously be seen. It is possible, indeed, to produce at pleasure a red congested appearance of the lung in any one of its surfaces, by letting the body lie for some time on its back, side, or face, and to bring about a similar result in any portion of the intestines by suffering it to hang in a depen-

dent position. Numerous experiments were made on this subject by Rigot and Trousseau; and the blood sometimes oozes in such quantity as to accumulate in the cavity in the form of a hemorrhage. These sanguineous congestions are formed, not only when the mass of the blood is considerable, but also after protracted diseases.*

These congestions are principally observed on the exterior of the body in the most dependent parts of the skin, such as the back and calves of the legs, which present a uniform livid red colour, disposed in stripes or patches. Red streaks, either parallel or intersecting each other, are also sometimes seen on the arms; thighs, thorax, and abdomen, and not confined to the dependent parts of the body; the vessels of all these parts, especially the veins, are found minutely injected with black blood; the streaks occur in the course of large veins, and seem to be the effect of the transudation of their blood staining the surrounding tissues. During the last moments of life, owing to the weakened action of the heart, there is less blood propelled to the surface, and it has a tendency to accumulate in the internal organs; the internal cadaveric congestions present a uniform red tint, disposed also in isolated spots, stripes, or patches; the blood escaping from its vessels forms effusions, and stains the neighbouring tissues; if there exist previously serous effusions, they become tinged with the colouring matter of the blood; there is also extravasation of the serous fluids; and effusions take place into the cavities of serous membranes or in the cellular tissue; the bile likewise transudes through the gall-bladder, and stains the surrounding parts. All these appearances are more particularly found in the membranes of the brain lining the posterior part of the skull, and in the posterior part of the spinal canal; in the lobes of the cerebellum and posterior lobes of the cerebrum; in the posterior portion of the lung; the most dependent portions of the stomach and intestines, and in the kidneys. These parts present sometimes a uniform deep red colour, resembling the most intense congestion.

At a later period, when putrefaction commences, various gases are disengaged, and particularly sulphuretted hydrogen, which penetrate the coats of the bloodvessels as well as all other tissues, change the colour of the blood, and produce the various tints of brown, livid, and green, that characterize putrefaction. These changes of colour are first noticed on the concave surface of the liver, in consequence of its vicinity to the transverse arch of the colon; they next manifest themselves in the abdominal muscles, and subsequently in the integuments.

Congestions after death are formed, therefore, in three different ways: by the gravitation of the fluids within their vessels; by transudation of the fluids through the parietes of the vessels

and imbibition of the neighbouring tissues; and by chemical affinities.

The nature of the first species of cadaveric congestion is sufficiently obvious not to require any explanation. The fact of the transudation of fluids through the membranous parietes of vessels, and of all animal tissues having in a certain degree the property of imbibition even during life, has been clearly established by the experimental researches of Majendie, Fodéré, and Dutrochet: the functions of exhalation and absorption seem to be, partly at least, carried on by transudation and imbibition. The vessels and serous membranes are, however, considerably less permeable to the fluids they contain during life than after death, which is partly attributed by Majendie to the current of circulation constantly conveying away the fluids before they can accumulate in any part; the solids are also endowed by their vital principle with a greater degree of density and power of resistance during life, whilst after death the physical laws acquire their full influence.

The patches and stripes of uniform red are the effect of this property of transudation and imbibition; the tissues appear as if soaked in blood and stained with it. This uniform red tint is frequently observed on the internal coat of the bloodvessels and of the heart; it is of a vermilion red in the arteries, and of a darker red in the veins: the redness penetrates all the coats of the smaller and thinner vessels, and extends sometimes to the adjacent tissues: the vasa vasorum of the large vessels are minutely injected. These appearances in the bloodvessels are almost constantly found at the end of twenty-four hours in the bodies of persons who have died from an obstructed state of the circulation, or from diseases in which the blood is preternaturally fluid. The small quantity of colourless or reddish serous effusion found in almost every body in the arachnoid of the brain and spinal marrow, in the pericardium, pleura, and peritoneum, thirty-six hours after death, is to be attributed also to transudation. Congestions and effusions from transudation occur most frequently in those diseases in which the blood is thin, and retains its fluidity after death, such as scorbutus, purpura hemorrhagica, and all diseases usually called putrid: they are seldom observed in the neighbourhood of large veins and arteries on account of the thickness of their coats; they are greatly facilitated by the rapidity of putrefaction, and therefore materially influenced by the heat and moisture of the atmosphere.

With regard to the effects of chemical affinities, it is important to remark that, when a portion of lung, intestine, or brain, presenting little or no vascularity, has been exposed for a short time to the atmosphere, it assumes a bright scarlet appearance, resulting from the arterialization of its blood, which, being thus more highly coloured, is apparently increased in quantity. We have already stated that the gases evolved by putrefaction give the blood a brown, livid, or green hue; the texture of the part becomes more friable and flaccid, and

* Andral, op. cit. vol. i. p. 83. This chapter contains a very full and interesting account of the occurrence of congestions and effusions after death.

these appearances have, we apprehend, been sometimes mistaken for gangrene. Further details of the cadaveric appearances will be found in Andral's *Pathological Anatomy*,* and in the works on Medical Jurisprudence by Fodéré, Paris, and Beck.

We have thought it desirable to describe at some length these cadaveric appearances, feeling the great importance of their not being mistaken for the effects of disease, especially with respect to forensic medicine. There is, perhaps, no point in pathological anatomy which has given rise to greater diversity of opinion, has proved a more fertile source of error, and remains yet more undetermined, than the exact nature of the morbid appearances which separately characterize congestions both active and passive, and inflammation. This is in fact a subject often surrounded with many difficulties, an ignorance of which has led to the erroneous practice of pronouncing hastily and indiscriminately as inflammatory, appearances of redness, injection and turgescence belonging perhaps only to either active, passive, or cadaveric congestion. We shall therefore point out, as far as we are enabled in the present state of pathological knowledge, the characteristic signs by which we can establish a line of demarcation in the dead body between these various morbid appearances.

1. The existence of various degrees of *redness* in any tissue, depending on minute vascular injection, is not alone sufficient to indicate inflammation, as redness is produced also by several forms of congestion. An increase of volume likewise is not always characteristic of inflammation; it may arise from the distended state of the vessels, or the slight serous effusions that occur in congestions both active and passive. Increase of volume may depend, moreover, on a morbid activity of the functions of nutrition and secretion, causing a diseased growth of texture without the necessity of any inflammatory action. Congested tissues become also more soft and friable in consequence of the greater quantity of fluids they contain. The redness and increased thickness of a membrane and softening of its texture cannot, therefore, be always considered unequivocal marks of inflammation.

The following are the only sure signs of genuine inflammation: considerable increase of vascularity with extravasation of blood or coagulable lymph, and the formation of pus or other morbid products, leading to a decided change in the structure of the part affected. The presence of all these signs at the same time is not, however, required: there are variations in this respect according to the texture of the part, the intensity and duration of the inflammation. A very minute injection, chiefly of the small arterial branches; a vivid red colour, disposed in dots or striæ occupying the whole thickness of the tissue, and not removable by pressure or ablation; spots of ecchymosis, occasioned by the rupture of some of the small vessels; effusion of blood on the

surface, or its infiltration within the texture of the part, are all characteristic of recent inflammation. The exudation of coagulable lymph, the secretion of pus, and the formation of ulcers, indicate a more advanced period of inflammation. This, however, is not constant, as both lymph and pus are sometimes poured out, and ulcers very rapidly formed in certain soft tissues, as, for instance, in mucous membranes. The organization of lymph and conversion into new tissues, the complete organization of abscesses, and the formation of purulent sinuses, point out inflammation of longer standing: the minute vascularity and redness have in this latter case generally disappeared.

2. Injection, redness, and patches of ecchymosis exist also in passive congestion; but the injection then is seated principally in the veins. The redness is of a dark-brown hue rather than florid; the blood extravasated is thin and fluid, and the red colour is easily removed by ablation; the texture of the solids is soft, flabby, and easily torn, and the condition of the whole body usually indicates a state of cachexia. Active congestions are distinguished from passive by the vascular injection occupying chiefly both the large and small arteries, the networks formed by their extreme ramifications being so minutely filled with blood as to impart to the tissue an intensely bright-red colour; the blood is generally very viscid, and the texture firmer than in passive congestion. This is a condition of parts bordering on active inflammation, although no distinct change of structure has yet taken place. It is often described as inflammation, and the mistake is not perhaps of much practical importance, since they both frequently give rise to the same local and constitutional symptoms, and require the same mode of treatment; the morbid appearances belonging to inflammation and active congestion are, moreover, often united in the same organ; active congestion is most frequently attended with serous effusions or hemorrhage; inflammation, more generally with the effusion of coagulable lymph and pus, or ulceration. It must, however, be acknowledged that the distinction between active and passive congestion is often extremely difficult, if not impossible; and it will be necessary in general to attend to other circumstances besides the morbid appearances; such, for instance, as the mode of death, whether it has been sudden and rapid, or lingering; attended with violent struggles, or tranquil: also the nature of the preceding disease, and the state of the other organs of the body. We may thus ascertain whether the venous system is generally congested or not; and it should be remembered that the parenchymatous and membranous organs are usually found gorged with blood after diseases of the heart and asphyxia, in consequence of the mechanical obstruction to the return of blood to the heart.

It is important, however, to remark that the morbid appearances indicating active or passive congestion, such as redness, injection, turgescence, and even slight effusions, which ex-

* Vol. i. article 4, p. 70.

isted during life, sometimes completely disappear after death. There can be no doubt that this may happen, because there are instances in which, although the skin or the eye presented some of these appearances during life, they have been found quite pale after death. When, therefore, there have been well-marked symptoms of congestive diseases during life, the absence of the usual morbid appearances after death is not always sufficient to destroy our belief in their existence. We know that nothing may be found in the brain after apoplexy from simple congestion, though such cases are not of frequent occurrence. The changes of structure induced by true inflammation, such as suppuration, ulceration, &c., are free from this source of deception.

3. A little attention will be sufficient to distinguish the cadaveric congestions arising from mere gravitation of the fluids, from those produced by disease; the vascular injection and redness is confined to the most dependent parts of organs, and is found in a number of organs at the same time, varying of course according to the position of the entire body, or of certain regions only; this should always be a subject of particular inquiry. A considerable degree of injection, therefore, confined to one organ, and especially not occupying its most dependent part, may fairly be attributed to disease. The redness, injection, and sanguineous or serous infiltrations resulting from transudation, occur at a later period after death; the tissues are of a uniform red, as if dyed with blood; the blood can sometimes be washed away by repeated ablation, or by maceration for some hours in water; but this will not be the case four or five days after death: If a considerable degree of sanguineous infiltration is observed in one organ only, some days after death, and if it be accompanied particularly with much injection of both its large and small bloodvessels, there is little doubt but that it is the effect of disease; but if similar appearances exist also in different other parts of the body, it is much more probable that they originate in the cadaveric transudation that attends putrefaction. There is frequently, however, great difficulty in forming a right judgment in such cases, and it is necessary to exercise the utmost caution and discretion on this subject when called upon to give evidence before a court of justice. The various appearances depending on the action of chemical affinities in a more advanced state of putrefaction are too well characterized to deceive any well informed observer.

In judging of the morbid appearances, it will be necessary to take into consideration:—
1. the period at which the body is examined;
2. the position of the part; 3. whether there existed any mechanical obstruction to the circulation during life; 4. the mode of death; 5. whether there were any symptoms of acute vascular disease during life.

Local symptoms of inflammation.—Inflammation has been described both by ancient and modern writers as characterized by four local

symptoms. These have been accurately noticed by Celsus: *notæ vero inflammationis sunt quatuor—rubor et tremor cum calore et dolore*.* These symptoms may not all exist in every case, but the greater number of them are usually present; they may assume also various respective degrees of intensity. In some tissues there is generally very little redness or swelling, but intense pain. The pain may be intense, although the inflammation is moderate, or the pain be slight and the swelling considerable. The heat also varies in the same manner, the inflammation being sometimes attended with little increase of heat, while the swelling is great. These four symptoms exist in a moderate degree in the first stage of the inflammatory process, sometimes described as sub-acute, and which we have distinguished from perfectly developed inflammation by the term *active congestion* or *congestive irritation*. It is only when these symptoms have acquired a certain degree of intensity, leading to morbid changes of structure, that they constitute, according to the view we have adopted, true inflammation.

Redness.—Some tissues are naturally red; their redness, therefore, must be preternaturally increased to become morbid. A quickened circulation may cause a temporary increase of redness, heat, and even swelling, which soon subsides, and is in this case only physiological; the increase of redness must therefore be permanent to be accounted morbid. The redness is manifestly owing to the increased quantity of blood in the diseased part distending the vessels, and penetrating into the minute vascular ramifications which previously conveyed only colourless blood. Mr. Hunter froze the ear of a rabbit and thawed it again; this occasioned considerable inflammation, an increased heat and thickening of the part: this rabbit was killed when the ear was in the height of inflammation, and the head being injected, the two ears were removed and dried; the uninflamed ear dried clear and transparent, the vessels were distinctly seen ramifying through its substance; but the inflamed ear dried thicker and more opaque, and its arteries were considerably larger. The redness sometimes partly depends also on the formation of new vessels, but this of course can only happen in advanced stages of inflammation. Preternatural redness alone is not sufficient to constitute inflammation; it must be accompanied with a certain degree of pain, heat, and swelling; for we have seen that it is a common attendant of congestions, active, passive, and cadaveric. Its intensity is very variable; some dense fibrous tissues, such as tendons and ligaments, exhibit very little redness when inflamed, having but few vessels; whilst in more vascular textures the redness is bright and florid, constituting one of the most prominent symptoms; as, for example, in some cases of *cynanche maligna*, in which the pharynx and tonsils are of an intense fiery red

* Lib. iii. cap. 10.

with burning heat and pain, in consequence of the extreme injection and distention of the minute vessels; when the blood, however, stagnates, the redness changes to a dark purple, indicating mortification. The same appearances are observed in gangrenous erysipelas. The redness may assume various tints, from a bright scarlet to a dark livid purple, with every intermediate shade. It may also appear in patches, stripes, streaks, or be uniformly diffused; it is generally greatest in one point, decreasing gradually as it extends, until it becomes imperceptible, or sometimes terminating abruptly. It may be made to disappear by pressure, but returns as soon as the pressure is removed.

Swelling.—The swelling is produced in the first stage of inflammation by the greater influx of blood; at a later period it is increased by the effusion of serum, the extravasation of blood, and the deposition of coagulable lymph or pus; the interruption of the absorption may also be noticed as one of its causes. The swelling often remains after the inflammation has disappeared, particularly when it has induced much change of structure. Swelling alone does not constitute inflammation; although one of its symptoms, it may be occasioned by many other causes, such as the displacement of a part, as in hernia, and the dislocation of a bone, by the effusion of blood or water, the accumulation of air, morbid growths, &c. To be inflammatory, it must be conjoined with pain or redness. The degree of swelling depends partly on the violence of the inflammation, and partly on the structure of the parts affected; there sometimes exists very little swelling, as in ophthalmia, and superficial inflammation of the mucous and serous membranes and also of the skin; the swelling is then irregularly diffused over a large surface; in other textures it may be considerable and circumscribed. Excessive swelling and redness in a part, without much heat or pain, is very likely to terminate in gangrene.

It is sometimes not easy to ascertain the existence and exact seat of swellings of the internal organs, particularly in the abdomen, and a considerable degree of habit and tact is generally required to avoid mistakes. The swelling may be fixed or moveable, pulsatile or not; it may be necessary to make the patient vary his position, or to lessen the fulness of the abdomen by emptying the bowels; the exact seat of the swelling also is to be considered, whether connected with the liver, stomach, bowels, or kidneys; situated in the mesentery, or merely in the abdominal parietes. A solid tumour sometimes pulsates in consequence of being in contact with the aorta; this must not be mistaken for aneurism. It is very important to remember accurately the natural relative position of the different organs; the same rule applies to the protrusion of tumours through the parietes of the thorax.

Whilst on the subject of swelling, we must

notice the accompanying changes in the consistence or density of the part. Some pathologists have advanced as a general proposition, that inflammation has the effect of hardening soft and softening hard textures, giving as an instance the increased firmness of hepatised lung, and the softening of inflamed bone. We conceive, however, that there is some inaccuracy in this statement, owing to the ideas attached to the terms in which it is expressed not being well defined. Almost all soft parts of the body feel harder to the touch at the commencement of inflammation, in consequence of the distention produced by a greater influx of fluids; but this increased firmness of the part is far from indicating any increase in the force of cohesion of its particles, or a real augmentation of density. A portion of hepatised is much more friable and easily broken down by pressure than sound lung, which, although more yielding to the touch, has a greater degree of elasticity and power of resistance. It is more correct, therefore, to say that recent inflammation has the effect of lessening the force of cohesion of all parts of the body both hard and soft. This remarkable property of inflammation will be fully considered in the article *SOFTENING*. When soft parts have been exposed to chronic inflammation, they often become hardened in consequence of new concrete products being deposited in their texture, or of its undergoing some change of structure by a slow and vitiated process of nutrition and secretion, as is exemplified in a variety of indurated tumours and morbid growths; in phlegmasia dolens; a peculiar form of hardening of the subcutaneous cellular tissue, and elephantiasis.

Heat.—The application of the hand to an inflamed part is sufficient to prove that its temperature is increased; the air expired, when the nostrils, throat, or bronchial membrane are inflamed, is so heated by passing over the inflamed parts as to feel burning. The sensations of the patient also indicate an increase of heat, although this is generally exaggerated in consequence of the morbidly increased state of the sensibility; in some nervous affections the patient complains of a sensation of burning heat, whilst the temperature of the part remains natural or is even diminished; there is sometimes a sensation of burning heat in gangrene, when the part is quite cold. The natural temperature of the body varies from 98° to 100° at the heart and on the trunk, but it gradually decreases as we proceed further from the heart, and as the parts become smaller and more exposed to the influence of the surrounding atmosphere; it is thus only 92° at the extremities of the body; this is a fact it will be important to remember in forming any estimate of the increase of heat in inflammation. Mr. Hunter concluded, from experiments he made, that the temperature of inflamed parts is but little augmented; he excited artificially inflammation in the chest, the abdomen, the rectum, and the vagina, without being able to discover

any great increase of temperature, the thermometer rising only to 101° ; in one case, however, it was as high as 104° in the abdomen; and in a case of hydrocele the heat of the tunica vaginalis, which was 92° at the time of performing the usual operation, rose to 98° after inflammation had come on. There must, we think, have been some source of error in these experiments, for in numerous experiments made since those of Hunter, the thermometer, when applied to inflamed parts in cases of erysipelas, phlegmonous swellings, &c. has been observed to rise as high even as 107° of Fahrenheit. It is well known also that the general temperature of the body may be very considerably increased in various states of disease, not always inflammatory. When making observations to ascertain the variations of temperature in fever, we have not unfrequently seen a thermometer placed in the axilla, or under the tongue, rise as high as from 105° to 107° : a similar elevation of temperature has been noticed in acute rheumatism, and during the convulsions of tetanus. There is generally a rise of temperature with any great local increased activity of the circulation. Sir E. Home observed the oviduct of a frog, when about to spawn, two degrees higher than the temperature of the heart. Dr. Granville states that, during parturition, he has occasionally found the temperature of the vagina rise to 120° , the elevation appearing to bear a proportion to the degree of action in the organ.* Every preternatural increase of heat is not therefore to be considered as inflammatory. In cases of fever, and especially of hectic fever, the whole body or certain regions, such as the cheeks and the extremities, may be of a burning heat for a considerable time, in consequence of a state of active vascular congestion, without any inflammation. There must be a certain degree of intensity and a certain duration of morbid heat, united with other symptoms, to constitute inflammation. Redness and swelling may also exist with very little heat or pain, and pass on to suppuration, as is the case in abscesses by congestion and other forms of chronic inflammation.

We can scarcely expect that any satisfactory explanation of the increase of heat in inflammation will be given as long as there are points in the theory of animal heat that remain involved in obscurity. As the variations of animal temperature constitute one of the most important morbid phenomena of inflammation and of many other diseases, the consideration of the various opinions that have prevailed respecting the source of animal heat, and the causes which regulate its variations in disease as well as in health, is a subject of peculiar interest to the pathologist.

The chemical theory of animal heat proposed first by Dr. Black, and greatly improved subsequently by Dr. Crawford,† was long con-

sidered to account in a perfectly satisfactory manner for all the varied phenomena of animal temperature, both in health and disease. The accuracy of this theory has, however, been called in question of late years by several able physiologists, who have drawn conclusions from their experiments tending to subvert every one of its main positions. The chemical theory assumed as fundamental facts, 1st, That the generation of heat in animals is the immediate effect of the chemical action of the air upon the blood in the lungs, leading to results strictly analogous to those of ordinary combustion; 2d, That oxygen and arterial blood have much greater capacities for caloric than carbonic acid and venous blood; 3d, That the temperature of the blood is the same on both sides of the heart, and in the large trunks of the pulmonic system; and that the evolution of heat throughout the body is the result of the capacity of the arterial blood for caloric becoming lessened when it is changed into venous, by which a portion of its latent caloric is set free.

The important fact of oxygen having a much greater capacity for caloric than carbonic acid has been denied by Delaroche and Berard; and the fact of the capacity for caloric of arterial blood being greater than that of venous has been disputed also by Dr. Davy. The experiments, however, for estimating the capacities of gases and fluids for caloric are of so delicate a nature, and liable to so many sources of error, that the conclusions of these two gentlemen are by no means considered as fully proved. It has been asserted also, as the result of numerous experiments, that the heat of the blood on both sides of the heart is not uniform, but that the arterial blood is warmer than the venous by one or two degrees: it must be acknowledged that this opinion seems to have a great weight of evidence in its favour.

The experiments, however, which would have most completely overthrown the chemical theory if their conclusions had been confirmed, were those of Mr. Brodie; they led to the conclusion, by maintaining artificial respiration in decapitated animals, that the generation of heat has no connexion whatever with the changes the air and blood undergo in the lungs, but is entirely dependent on the influence of the brain and nervous system.* Legallois having, however, performed experiments of a similar description, arrived at conclusions directly opposed to those of Mr. Brodie, and tending strongly to confirm the opinion of the evolution of heat always bearing a relation to the consumption of oxygen.† The inaccuracy of Mr. Brodie's conclusions was further clearly established by the investigations of Dr. W. Philip, who pointed out several important sources of error in his experiments. While, however, it is admitted by Dr. W. Philip that the action of the

† Ann. de Chim. et Phys. tom. iv. p. 5-113.

air upon the blood in the lungs is the great source of animal heat, he has been led to conclude by some ingenious experiments, that its extrication from the blood throughout the system depends on the direct action of the nervous influence on the blood, and that the generation of heat may therefore be regarded as a kind of secretion.*

The advocates of the chemical theory have differed with respect to the part of the animal economy in which the combination of the oxygen of the air with the carbon of the blood takes place. Dr. Crawford maintained that the carbonic acid is formed in the lungs; that the heat evolved by its production is absorbed and becomes latent in consequence, as before mentioned, of the great capacity for caloric of arterial blood; and that it is again set free on the blood being changed into venous. Lagrange and Hassenfratz conceived that the air is absorbed by the blood in the lungs, and that the combination of its oxygen with the carbon of the blood takes place in the course of circulation, leading in this way to a gradual evolution of heat. Dr. Edwards has adopted this opinion, and supported it by experiments which appear extremely conclusive. Mitchel and Faust, however, having lately made in America some highly interesting experiments on the *endosmosis* of gases, consider that they have ascertained, beyond all doubt, that the carbonic acid is generated in the lungs.† If it be true, as stated by some able chemists, that the most delicate analysis can detect no carbonic acid in venous blood, this would at once prove fatal to the opinion of Lagrange.‡

On the whole the weight of evidence seems to be still greatly in favour of Dr. Crawford's theory; and although doubts may have been thrown out on the accuracy of some of his fundamental conclusions, none of them have yet been successfully controverted. It appears highly probable that no theory can ever be established without a due reference to the connexion which respiration has with the production of animal heat. It must, in the meantime, be admitted that the temperature of a part is not always in proportion to the strength and rapidity of its circulation, and that there are other circumstances, not hitherto well understood, by which the phenomena must to a certain extent be influenced: this is particularly the case with respect to the circumstances that influence the extrica-

tion of heat, and regulate the ever varying changes of temperature in different parts of the body. In some cases, for instance, of gouty inflammation, the heat of the part feels extremely pungent to another person, although there is not the least symptom of any increased influx of blood; the heat of the surface of the body is very high in some nervous fevers in which the vascular action is only moderately increased. Dr. Hastings states that he has seen several cases of fever in which the circulation was even remarkably slow, the pulse being only 45 when the temperature of the body was 105°; and that the heat has also been 100° in cases of hydrocephalus with a pulse at 60 or 70.* There is great reason to believe that the influence of the nervous system over the evolution of heat throughout the body is very considerable, especially in some states of disease; and if this be a well-founded conjecture, it would enable us to explain in a perfectly satisfactory manner several of the phenomena of this interesting process, which cannot so well be accounted for on chemical principles.

There is one circumstance, besides chemical action, which must, we conceive, have a considerable degree of influence in modifying the animal temperature, and which appears to us to have been hitherto too much overlooked. The various materials of which the body is composed are undergoing, during the process of assimilation, disassimilation, and secretion, an incessant change of state; some passing from the gaseous to the fluid, and from the fluid to the solid state, whilst others experience similar changes in an inverse order. These variations of density must necessarily be attended with both a considerable extrication and absorption of caloric, partly, no doubt, under the influence of chemical and electro-galvanic agency. It is, therefore, reasonable to suppose that the diffusion of animal heat throughout the body is in some measure connected with the operations, physical, vital, and chemical, constantly going on in the extreme vessels; and we shall probably never be able to construct any perfect theory of animal heat until we are better acquainted with the functions of these vessels. It is well known that every material disorder of the functions of nutrition and secretion modifies the temperature of the body: when the powers of assimilation exceed those of disassimilation, and the function of nutrition is in great activity, the faculty of producing heat is considerably increased; while, when the waste of the body surpasses its nutrition, the faculty of producing heat is weaker. Thus, in healthy individuals in the prime of life this faculty is greater than in old and sickly people: this is likewise exemplified by the cooling effects of the evaporation of the cutaneous perspiration, and, in dogs, of the pulmonary exhalation. In inflammation there is a great accession of nutritive fluids, which, becoming condensed, necessarily give out heat, whilst absorption and disassimilation are completely suspended; this

* It has been ascertained by Prevost and Dumas, from some very valuable experiments upon the proportional quantity of globules contained in the blood of different kinds of animals, and of different parts of the sanguiferous system in the same animals, that there exists an exact ratio between these globules and the temperature of the animal, which is highest in those whose blood contains the largest proportion of globules.

† American Journal of Med. Sciences, vol. vii. Philad., Nov. 1830.

‡ A good account of the various opinions brought forward on the subject of animal heat, and of their respective merits, will be found in Dr. Bostock's valuable Elementary System of Physiology, vol. ii. p. 243.

* Hastings on Inflammation, p. 110.

must inevitably create a considerable preponderance in the extrication of heat over its absorption, and contribute to raise the temperature of the part.

Dr. Edwards has adopted the conclusion, from his beautiful experiments *On the Influence of Physical Agents*, that the production of animal heat is to be referred to a special power possessed by the living body, a kind of calorific function, which varies according to age, states of health or disease, and climate; that this power of generating heat is intimately connected with the respiratory, circulating, and secreting functions, and that it cannot suddenly undergo any permanent alteration during health. Dr. Edwards's interesting experiments admit of some important applications in pathology. The power of generating heat is distinctly proved to be less in children than in adults by nearly five degrees of Fahrenheit, and their temperature can, therefore, only be maintained at the standard of health by artificial heat, contrary to the commonly received pernicious opinion that children resist cold better than adults: this is fully confirmed by the great tendency observed in children to become cold and pallid, and to be affected with other symptoms of exhaustion, from the incautious use of bleeding and purging. The faculty of producing heat diminishes as the heat from external agents increases, and *vice versa*; so that this faculty is greater in the inhabitants of cold than in those of hot climates. But the power of generating heat is not capable of being either increased or diminished *suddenly* during health; hence the injury sustained by all sudden changes of the atmospheric temperature. When an inhabitant of the north removes to the south, his faculty of producing heat being too great in relation to the climate, there is an excess of heat in his system, by which he is greatly predisposed to inflammatory affections; and this will continue to be the case until his power of generating heat has been gradually lowered, so as to become adjusted to the climate: a change of this description is found to require in general about two years. Recent experiments, made with great accuracy, prove that animal temperature is not, as was supposed, equalized all over the globe. Dr. John Davy ascertained that the inhabitants of Ceylon have a higher temperature than Europeans by nearly two degrees; this is the effect of the heated atmosphere in which they live, and would be still greater were it not counterbalanced by the circumstance of their generating much less heat than Europeans.*

Dr. Edwards observes, also, that the faculty of producing heat is considerably modified by disease. In all inflammatory diseases it is greatly increased; in chronic and organic diseases, especially of the organs of respiration and circulation, it is often much lowered. In-

dividuals labouring under such diseases are consequently observed to suffer severely from cold, and to be in general benefited by emigration to a warmer climate, where a diminished power of generating heat is more compatible with the enjoyment of good health.

Pain.—Pain has a highly important influence in inflammation; it varies from the slightest increase of sensibility to the most violent suffering. It may be induced by an irritation of the nervous system without any corresponding increased action in the vascular system; severe spasm causes intense pain, as is seen in cramps. There are excruciating neuralgic pains of long continuance, as in tic douloureux, without any accompanying inflammation. In consequence, however, of the intimate connexion between the functions of the nervous and vascular systems, and especially those of the minute vessels, nervous irritation is generally attended with increased vascular action. We have already seen that the first effect of the application of irritants to the living body is the excitement of pain, and that this is soon followed by an accelerated circulation and increased flow of blood to the part. It is not easy to explain why the action of irritants is sometimes confined to the nervous system, unless we can suppose that there is some state of disease affecting exclusively the structure or function of the nerves.

The pain in inflammation is either to be attributed to the direct irritation of the nerves by the exciting cause, or to their compression in consequence of the over-distention of the vessels, or the stretching of the fibres of the part: the pain is often increased with each dilatation of the arteries, constituting what is called pulsatile pain. There are great variations in the degree and nature of the pain, depending on the texture of the part, the number of its nerves, the violence of the inflammation, nature of the irritating cause, &c.: it must be acknowledged, however, that until we are better acquainted with the structure of the nerves and nature of the nervous principle, we can scarcely hope to account for all the varieties of their morbid excitement.

It is generally very acute in parts largely provided with nerves, and especially when they are delicate and pulpy; for the degree of pain is rather in proportion to the number of nerves terminating in a part, than to the size of the nerves passing through it. In parts of a dense and unyielding texture the pain is also generally very severe, although they have but few nerves, and are not naturally endowed with much sensibility: this is owing to the great compression of the nerves by the distended vessels. We see this exemplified in bone, tendon, ligament, all fibrous textures, and even the hard cartilaginous surfaces of joints, which become red and extremely painful under inflammation: the same takes place in soft parts whenever surrounded by fibrous bindings. When there is great tension, the pain is often so excruciating as to disturb the whole nervous system and bring on delirium; hence the good effects of relieving the

* Some observations having been made recently by one of our medical officers on the coast of Africa on the comparative heat of Negroes and Europeans, it was found that the temperature of the former was several degrees higher than that of the latter.

tension by practising incisions even in the early stages of inflammation before the formation of matter: they are often followed by the instantaneous remission of fever and delirium. This is probably the reason of the inflammation of serous membranes, which are generally spread out tightly, being attended with much more violent pain than that of mucous membranes. Mucous membranes are also much less sensitive than the skin, and their inflammation is often not attended with much pain: this is one reason for the inflammatory affections of the mucous membrane of the alimentary canal having been so often overlooked. The degree of pain is not always therefore in proportion to the original sensibility of the part, but depends also on its tense and unyielding character.

The pain is usually pruriginous, pricking, and burning in the skin; acute and shooting in serous membranes; dull and throbbing in cellular and parenchymatous organs; lancinating in cancer and malignant tumours; obtuse and heavy in glands and bones. A sense of weight and throbbing generally indicate a tendency to suppuration, and the pain usually subsides on the formation of matter, particularly if it has a free issue. The pain is in some instances continued, in others periodical: the sensibility of some of the organs of sense, such as the nose and mouth, is diminished during inflammation, whilst the eye and the ear, when inflamed, become exquisitely sensible. The pain is sometimes so slight, that it amounts only to a morbid soreness or tenderness on pressure. Besides pain, the sensibility of the part is morbidly increased to all external impressions, so that those which before gave pleasure become painfully exciting. Most of the internal organs perform their functions during health without transmitting any perceptible impression to the sensorium; but when inflamed, we become immediately conscious of their various actions, in consequence of these being attended with uneasiness and pain: we can then distinctly *feel* that we have a stomach, heart, lungs, &c.: these sensations are always sure signs of a state of disease, and intended no doubt as warnings that we may avoid persisting in the use of what might prove injurious.

The pain arising from mere spasm is generally lessened by pressure, as is observed in colic; and this forms a good distinction from inflammatory pain, which pressure aggravates. The pain of inflammation is, however, chiefly increased by sudden and partial pressure; for frequently a gentle pressure of the whole of the inflamed part gradually increased, can be endured without pain, and even mitigates it.* One of the effects of general pressure is to diminish the influx of blood, and lessen in this way the swelling, the heat, and all the other symptoms of inflammation. General and graduated pressure has on this account

been recommended, and sometimes successfully applied as a remedy: it has been used to this effect by Dr. Balfour in rheumatism, by Mr. Carmichael in cancer, and Mr. Velpeau in erysipelas. We have witnessed good effects from it in some cases, but have seen it aggravate the symptoms in others.

The sudden disappearance of intense pain in a highly inflamed part often indicates the approach of gangrene. Very severe pain has a great influence in inflammation by the morbid sympathies and constitutional disturbance it excites.

Some caution is frequently required in ascertaining the existence of pain. Under certain states of general nervous irritability, the patient complains of tenderness in whatever part of the body pressure is applied; this tenderness is sometimes greater, or perhaps entirely confined to certain regions, and more particularly to the epigastrium and the hypochondria. There is in some nervous persons at all times a great intolerance of pressure in the epigastrium. We have known a hasty and superficial examination in such cases lead most erroneously to the conclusion of inflammation being present, and to the consequent adoption of active remedies, where there was no actual disease. Mistakes of this kind are by no means of rare occurrence in the present times, since the minds of practitioners have been so exclusively occupied with the idea of the great prevalence of inflammatory diseases over all others, and especially of gastro-enteritis; and persons have in this manner not unfrequently been subjected, without the least occasion, to long courses of bleeding, purging, and mercurial treatment.

The presence of pain or tenderness alone without any of the concomitant symptoms, is never sufficient to constitute inflammation; by diverting a little the patient's attention, and then gradually repeating the pressure, it will often be found that his first complaints were greatly exaggerated. There is in general much difficulty in ascertaining the seat of pain in infants, as they merely exhibit general signs of suffering, without being able to describe their sensations. It will be necessary in such cases to watch carefully the expression of the countenance for the ordinary indications of pain, when pressing the different parts of the body: infants are sometimes observed to carry frequently their hands to the part of the body that is affected.

Pain, even of the most intense description, may also become latent, in consequence of the sensibility of the sensorium being impaired by disease. This not unfrequently happens in febrile affections when the head is much affected; local inflammations, which at first complicated the fever, may thus be supposed to have subsided, while in reality they are only masked, and are proceeding in their destructive course: it is necessary, in order to guard against this deception, to make daily, in such cases, a minute and careful examination of the condition of the principal viscera.

* Dr. Elliotson's Lectures on Inflammation, Med. Gaz. Nov. 26, 1831, in which a clear and comprehensive description is given of the local symptoms.

There is another source of delusion with respect to pain: it is sometimes felt at a distance from the seat of the inflammation in a greater degree than in the diseased part. In such cases the pain is generally conveyed by nerves passing through the inflamed part to other remote parts, in which they terminate. We have familiar instances of this peculiarity in the morbus coxarius, in which the only pain complained of is frequently in the knee, and sometimes likewise in sciatica.

There is a particular expression of countenance characteristic of the existence of pain in each of the different viscera; the contraction of the forehead and eye-brows, combined with a wild, staring, or heavy expression of the eyes, are the usual indications of pain in the head. The distention of the *alæ nasi*, contraction upwards of the commissures of the lips, and of the cheeks, and protrusion of the eyes united to heaving of the shoulders, point out pain in the thoracic viscera. A falling in of the cheeks, contraction downwards of the angles of the mouth, an elongation and pinched appearance of the features, with sunk eyes and pallidness, indicate abdominal disease. There is an expression of great dejection in all chronic diseases of the urinary organs.

Besides the local symptoms just described, there are others which have reference to the disturbance of the functions of the organs affected. Thus, inflammation of the brain is attended with delirium, vertigo, coma, convulsions, and paralysis; inflammation of the larynx with a shrill, crowing, hoarse, or feeble voice, and difficulty of breathing; that of the pharynx with difficult deglutition; that of the lungs with dyspnœa, cough, and various kinds of expectoration; hepatitis with pain in the shoulder and larynx, besides pain, heat, and fulness in the right hypochondrium; gastritis with nausea and vomiting, besides fulness, heat, pain, and great tenderness in the epigastric region; nephritis with retraction of the testicle and vomiting; panaris with swelling of the glands of the axilla, &c. When the inflammation affects exhaling and secreting organs, there is a change in the quantity and quality of the secretions; they are at first diminished, or even suspended; they then return altered perhaps in colour, thickness, or smell.

In the inflammation of internal organs these functional and sympathetic symptoms are often of the greatest value, as the more ordinary local symptoms are mostly beyond the reach of our observation. When the inflammation is extensive and severe, the functions of other organs are also disturbed; the whole constitution may become more or less affected; and this affords another class of symptoms called *constitutional*, from which we often derive considerable assistance in our diagnosis. These form the next subject of consideration.

Constitutional symptoms of inflammation.—It has already been stated in the experimental inquiry into the nature of inflammation, that the action of stimuli on the living body was not

always limited to the part to which they were applied, but extended frequently to the whole animal economy, exciting various degrees of disturbance in its several functions. The existence and nature of this constitutional derangement was demonstrated by several experiments.

Inflammation may extend in several ways beyond its original seat. By continuity:—when it extends along the surface or throughout the substance of the same tissue: thus there is a great tendency to the rapid diffusion of inflammation along the surface of the skin in erysipelas; and the same is observed in the inflammation of mucous, serous, and fibrous membranes. By contiguity:—when it is communicated to adjacent tissues of a different nature: the inflammation often extends in this manner from serous membranes to the organs they invest. The facility with which inflammation spreads by contiguity depends, in a great measure, on the disposition of the connecting cellular membrane: when loose, it transmits the inflammation rapidly from one part to the other; but when dense, it appears to oppose strongly the propagation of the disease. It was a remark of Laennec, that congestions and gangrene had a greater disposition to spread by contiguity, and acute inflammation by continuity.

The local extension of inflammation is, on the other hand, checked by differences in the texture, the vital properties, and in the functions of the various organs and tissues of the body; and we may add, that general tendency in all living matter to resist the destructive effects of disease. One of the means by which this is effected is the effusion of coagulable lymph, and contraction of adhesions around the seat of the inflammation; so that the continuity of the parts is interrupted, and the disease circumscribed.

The communication of inflammation to parts of the body *remote* from its original seat takes place in two different ways, either through the medium of the circulation, or that of the nervous system. It has been satisfactorily proved, by direct experiment, that when deleterious substances are inserted into any part of the body, they are sometimes absorbed into the bloodvessels, and conveyed by the blood to remote parts, where they excite various diseased actions.* We have further demonstration of this being the case from numerous pathological facts, as in the morbid effects of various animal and other poisons, which it would be difficult to explain in any other manner than by the absorption of the morbid matter. It is, therefore, very generally admitted that the blood is the vehicle of a great many morbid principles; and that the deterioration of its qualities is to be placed among the most frequent causes of disease. In inflammation it is easy to conceive, when it is either of an unhealthy character or the result of a specific cause, how the morbid

* Majendie's Physiology, p. 347, Milligan's translation.

products of the local affection, being absorbed into the blood and circulated with it throughout the body, should sometimes excite inflammation in distant organs, and disturb the general health. Morbid impressions are, however, transmitted also from one part to another by the nervous system; and nervous sympathy is therefore another great cause of the constitution being so frequently and variously affected by local inflammation. We think it, therefore, desirable to offer here a few observations on the influence of sympathy.

The structure of the human body is very complicated, its elementary materials being so arranged as to constitute an assemblage of tissues and organs having distinct physical and vital properties; these tissues and organs act reciprocally on each other, producing by their combined operations the complex phenomena of life. Every living part of the body has a general sympathy with the whole system, or a particular sympathy with certain parts of it; and the functions of each part are more or less essential to the healthy action of the whole. The influence of these reciprocal sympathies is, therefore, very considerable, especially in disease. It is through the medium of the brain and nerves that sympathies are established between all parts of the system: receiving morbid impressions from diseased parts, the nerves transmit them to the other organs of the body, and in this manner become the source of an infinite variety of both local and constitutional morbid phenomena.*

Inflammation in one part of the body may also disturb the functions of the others by its direct influence on their circulation, independently of any nervous sympathy. The great accumulation of blood in an inflamed part may be the means of depriving another of its usual supply of blood; thus the inflammation of internal organs attracts sometimes the blood from the surface towards the centre of the body, creating coldness and pallidness of the skin; the lower extremities are likewise cold in cases of determination of blood to the head; on the other hand, if the regular return of the blood to the heart be prevented by the inflammation of any of the central organs, such as the lungs, heart, large vessels, &c. this will cause it to accumulate in remote organs, and impede their functions. These unequal distributions of blood from the mere mechanical derangement of the balance of the circulation are of frequent occurrence, and a much greater source of constitutional derangement than has generally been supposed: they may be looked upon as a species of *sanguineous* sympathy.

There exists a strong sympathy also between the different organs engaged in the same func-

tion: when the stomach, for instance, is in a state of disease, all the other organs belonging to the digestive function are more particularly predisposed to sympathise with it. One eye has also been known to become inflamed through mere sympathy with inflammation that existed previously in the other. This kind of sympathetic influence has been called *sympathy of function*. It has been advanced by Bichat that similarity of structure chiefly is a great source of sympathy, and that, for example, when a serous or fibrous membrane or a muscular organ was inflamed in one part of the body, there was a strong tendency to inflammation of the same textures in every other part of the body.

The various morbid sympathies and constitutional symptoms to which they give rise, are considerably modified by those peculiarities of constitution which have been termed temperaments and idiosyncrasies. The temperaments are formed by a preponderance in the development and activity of certain tissues over others in the same body; they may be divided, to suit practical purposes, chiefly into four—the sanguineous, bilious, phlegmatic, and nervous; there are, however, various combinations of these, forming a number of subdivisions. By idiosyncrasies are meant peculiarities of constitution belonging only to one or a few individuals; these are innumerable, often discovered only by accident, and in general difficult to explain. Thus certain alimentary and medicinal substances affect some individuals in a manner totally opposite to their general mode of action. There are also predispositions of the constitution to certain forms of disease, which are called *diatheses*. Having premised these general observations on the different modes of extension of inflammation on sympathetics and temperaments, we shall proceed to the important consideration of, 1st, the influence of the constitution on local inflammation; and, 2dly, of the various forms of constitutional derangement induced by inflammation.

Influence of different states of the constitution on local inflammation.—We have already had occasion to remark that every living part seems to be endowed with an inherent faculty of resisting, to a certain extent, the effects of disease. We are unacquainted with the nature of this faculty: it cannot be satisfactorily accounted for by structure, and is to be referred most probably to the immediate influence of the vital principle; it has been designated accordingly by the ancients *vis medicatrix nature*. It is in consequence of this faculty of resistance, that whenever a living part has sustained any injury, either from external or internal causes, an increased activity is soon observed to take place in most of its vital actions, and a process *essentially vital* is set up, by which the effects of the injury are often prevented, removed, or repaired.

The faculty of resisting disease is observed to exist in different degrees in different individuals, and in the various parts of the same body. It is generally greater or less in proportion to

* See Dr. Thomson's account of particular sympathies in his Lectures on Inflammation, and also some excellent remarks on the influence of local and general sympathies in the work on inflammation by Mr. James, Second edition.

the strength and soundness, or weakness and unsoundness, of the constitution. In strong and healthy constitutions, there is in general only moderate predisposition to inflammation, even after the severest injuries, which are repaired by a mild though efficient degree of inflammatory action. But in individuals whose constitutions are either originally weak, irritable, or unsound, or have been rendered so by long-continued disease, the tendency to resist inflammation is much weaker, and when excited, it is generally more violent, spreads more rapidly, and is less easily removed. It is also well known that parts of the body having a low vitality, such as tendons, ligaments, bones, &c. resist inflammation much less effectually than those more highly organized. It is highly important, therefore, in a practical point of view, to remember that there are circumstances in which the violence and spreading of inflammation may be greatly increased by a state of general debility.

A disordered state of the constitution operates not only in favouring the increase of inflammation, but opposes also a formidable obstacle to the establishment of those restorative processes by which it is brought to a favourable termination. The principal sources of disorder in the constitution by which local inflammation is liable to be affected, may be referred to the following: a state of general plethora combined with an over-degree of activity in all the functions of life—an opposite condition of the system arising from deficient nourishment, and attended with general languor and debility—the vitiation of the qualities of the blood and other animal fluids, the effect either of bad food and air, or of the introduction into the animal economy of morbid and other deleterious substances—a disturbed and irritable condition of the nervous system—a disordered state of the digestive function, and that in general of any of the vital functions—organic disease of an important organ—and, lastly, a predisposition to some form of specific disease, such as scrofula, gout, cancer, &c. Innumerable examples of the influence of all these morbid conditions of the constitution upon local inflammation might easily be adduced, were it not incompatible with the limits of this article; but we shall have occasion to enlarge upon this view of our subject when treating of the constitutional effects of inflammation.

There is one highly important practical rule to be deduced from the preceding considerations, namely, that from whatever cause the disorder of the constitution may proceed, the attention of the practitioner must be first directed to the amendment of the general health before he can hope to succeed in removing the local disease; this latter must in fact be treated by constitutional remedies; for if local applications only be relied upon, they will seldom be found of much avail. The merit of having called the attention of the profession to this important principle in pathology, is due, as already observed, to the late Mr. Abernethy, who directed more especially his inquiries to

the influence of the state of the digestive organs over local diseases: we must refer the reader for fuller details on this important subject to Mr. Abernethy's valuable writings.*

Various forms of constitutional disturbance induced by inflammation.—Inflammation of any parts of the body, whenever it is very intense, excites a disturbance in the functions of the heart, brain, and stomach, characterised by a series of morbid phenomena which have received the name of *symptomatic* or *sympathetic fever*. This morbid state of the constitution reacts, however, powerfully in its turn on the local inflammation by which it has been excited, so that there exists the most intimate connexion between the local affection and constitutional reaction. This is a circumstance leading to highly important consequences, for the sympathy of the constitution is generally the result of a salutary effort of the powers of life to assist in arresting the progress or removing the effects of the local disease, and the accomplishment of this desirable end depends in great measure on the local and constitutional morbid actions being duly balanced.

Many proofs can be adduced in support of this mutual dependence of the local and constitutional affection upon each other. The reaction of the constitution corresponds generally in degree with the strength of the local inflammation, the former being aggravated or diminished in the same proportion as the latter increases or lessens. When the reaction is excessive, it tends to aggravate the local disease: when, on the contrary, the reaction is deficient, the local affection may either remain stationary and assume a chronic character, or it may increase rapidly, and affect by sympathy remote parts of the body, as sometimes happens in the unhealthy inflammation excited by morbid effluvia or animal poisons. It is well known that if the constitution becomes much disordered, or if its powers happen to fail during the progress towards restoration of any wound, the inflammation of the wound, which was before perfectly healthy, either assumes immediately an unhealthy character, or entirely disappears, leaving the part even sometimes in a state of mortification. The discharge from a wound, moreover, is generally scanty, and never of a healthy character as long as the symptomatic fever continues high; but as soon as the fever abates and the general secretions are restored, the discharge becomes more copious and healthy. If, on the other hand, an individual reduced to a state of extreme debility from severe local disease, be seized with inflammation of a vital organ, he will sometimes bear with impunity a degree of general depletion which would have been previously sufficient to destroy him.† The preceding instances, to which many others could easily be added, will be sufficient to establish the fact of the existence of the closest sym-
 *

* On the Constitutional Origin of Local Disease.

† James on Inflammation, p. 46.

thy between the local and constitutional morbid actions.

The constitutional reaction not only varies, as already stated, in degree, but also in its nature; and the correspondence is likewise maintained in this respect between the local and constitutional affection. The character or type of the symptomatic fever is influenced chiefly by the following circumstances in the temperament and previous state of health of the individual,—the seat and extent of the local affection, and the nature of the exciting cause. In individuals of a sanguineous temperament there is generally a strong reaction of the vascular system, and the type of the fever is essentially *inflammatory*, and seldom attended with much danger. In those of a nervous and irritable temperament, or whose constitutions have been weakened by disease, the fever is chiefly characterized by considerable disturbance of the *nervous system*, and by a variety of anomalous and untoward symptoms; there is frequently in this form of fever a degree of over-excitement followed by rapid collapse. The character of the reaction, however, may be entirely derived from the seat and extent of the inflammation, or the nature of the exciting cause: thus the inflammation of fibrous tissues, that consequent upon extensive injuries, or poisoned wounds, &c., generally induces very great disturbance of the nervous system, and the most dangerous forms of sympathetic fever, even in robust and healthy subjects. It is worthy of remark in these cases, that whenever we can change the character of the local disease by substituting healthy for unhealthy inflammation, the character of the constitutional affection becomes also immediately impaired.

There is another important form of constitutional affection that differs widely from the preceding; it is characterized by the total absence of all reaction, and by a state of direct prostration and rapid sinking of the powers of life; this dangerous affection may also depend either on the temperament and previous state of health, the seat and extent of the local affection, or nature of the exciting cause.

The constitutional symptoms present other variations with respect to their character or the order of their appearance; they may be remittent or intermittent; precede the appearance of the local symptoms, occur simultaneously, and sometimes only after them. The character of the fever may be modified by the inflammatory and nervous types being combined in an almost infinite variety of degrees. It would be impossible, however, to describe every shade of difference; and we think it sufficient therefore for practical purposes, to adopt the division of the constitutional affections into, 1st, *inflammatory reaction*; 2d, *nervous reaction*; and 3d, *the state of direct prostration and rapid sinking without reaction*. We must be understood not to use the terms inflammatory and nervous in an exclusive sense, but as only implying that such is in each case the predominant nature of the reaction.

1. The appearance of the constitutional as well as of the local symptoms does not always immediately follow the introduction of a morbid agent into the system; a period of variable duration often intervenes, which may be considered as one of *incubation*. This important period is sometimes characterized by a certain degree of constitutional derangement; the symptoms of this derangement being, however, obscure, have not hitherto obtained the attention they perhaps deserve, and are often unnoticed both by the patient and the practitioner. There may be a feeling of general uneasiness and lassitude; pains in the limbs, disturbed sleep, sometimes headach, depression of spirits, slight alternations of chill and heat, a decrease of appetite, a bitter taste, clammy and furred tongue, a tendency to constipation, and turbid urine: other symptoms, besides the preceding, might no doubt be sometimes detected by close observation; they all indicate the latent influence of some morbid cause, acting on the entire system, and depressing more especially the functions of the circulation and innervation.

After the period of incubation has lasted a variable interval of time, the local symptoms of inflammation generally make their appearance; and these are followed sooner or later by a more marked degree of constitutional disturbance. The patient is seized with rigor, nausea, or vomiting; the face is pale, the skin cold and rough, the pulse small and frequent: to this depression succeeds a general reaction, characterized by a dry burning heat of the skin, headach, flushing of the face, pain in the loins, restlessness, great general anxiety, soreness of the whole body, and sometimes delirium. The pulse is full, hard, and frequent; the breathing hurried; the secretions become diminished and altered; the tongue is furred, dry, and red, especially at the edges and point; there is loss of appetite and great thirst; the bowels are confined; the urine is scanty and high-coloured, but it remains clear and emits a strong animal smell. The blood drawn from the veins is buffed and cupped, a state of the blood which has already been fully described. These symptoms vary in severity and duration according to the seat and intensity of the inflammation.

In all inflammatory affections there are also daily variations in the acuteness of the symptoms, constituting paroxysms of exacerbation and remission. The exacerbations generally occur towards night, when there is an increase of the pain, heat, and swelling, and an exacerbation of all the febrile symptoms. As the morning approaches, the symptoms lessen in severity, and there is either a partial or complete remission of fever, characterized by an abatement of the pain, and frequency of the pulse, and by the breaking out of moisture on the skin.

Besides these daily variations, the course of inflammatory affections may be divided into three periods—one of invasion, one of increase, and one of decline. The febrile symptoms already described persist, varying only

in intensity, until the inflammation has reached its height. During the period of decline they are variously modified according to the mode of termination of the local disease: if by resolution, there is a gradual abatement of the fever, attended usually with a restoration of the diminished secretions and critical evacuations from some of the excretory organs. Thus, as the local symptoms decrease, the frequency of pulse and heat of the skin gradually subside; the tongue becomes moist and clean; the thirst, restlessness, general pains, and delirium disappear; there is a variety of critical evacuations by profuse sweat or a copious flow of urine; by diarrhœa, expectoration, ptialism; or by spontaneous hemorrhage from the nose, stomach, bowels, kidneys, or uterus. These critical discharges occur either singly or are variously combined; they are frequently preceded by a severe general rigor and exacerbation of all the constitutional symptoms, *exacerbatio critica*, which is sometimes mistaken for an aggravation of disease, but is soon followed by profuse sweat and other evacuations, which lead to a complete remission of the fever. The variations in the state of the urine deserve particular attention; a full account of them will be found under the section *Resolution*. The ancients attributed these critical evacuations to the expulsion of the morbid matter, by which blood and humours were deprived of their inflammatory and other deleterious properties; and they considered them as being strictly analogous to the suppuration of phlegmon.

When, however, the inflammation terminates in suppuration, there is during the period of decline an imperfect remission only of the constitutional symptoms; the fever returns after a deceitful suspension or partial abatement of its symptoms for a few days. It assumes a more decidedly remittent character; slight paroxysms of rigor are experienced towards evening or after the meals, followed by flushes of heat, particularly in the cheeks, hands, and feet; also thirst, restlessness, and frequency of pulse; the exacerbation increases until towards morning, when it is relieved by profuse perspiration, and there is a well-marked remission of fever during the forenoon; this constitutes *hectic fever*, which has been fully described in the article *FEVER*.

The sudden cessation of violent pain attended with prostration of strength, increased rapidity, weakness and irregularity of the pulse, cold clammy sweat, and delirium, denote the fatal termination by gangrene.

It is important to observe, that when the period of increase of the inflammation has been attended with high general excitement, that of decline is sometimes marked by a great and dangerous collapse of the powers of life, particularly in old people and young children. The probability of such an occurrence should be carefully kept in view, in prescribing active remedies during the violence of the disease in such subjects; for otherwise a state of fatal sinking or dropsical effusion may be brought on by too active a treatment, although

it may perhaps have appeared justified at the time by the immediate relief it afforded. If old people were formerly stimulated to death under the mistaken notion that they are not subject to inflammation, we suspect that some in the present day may have sunk under the indirect effects of excessive bleeding, owing to a disregard of the practical precept just alluded to.

The series of constitutional symptoms we have just described are those of the simplest form of inflammatory fever. This fever is generally induced by the development of common acute inflammation from either accidental or constitutional causes; it affects most commonly robust healthy individuals, of a sanguine temperament, in whom there is a redundancy of rich blood—a condition of the system which has received the name of inflammatory diathesis. The simple inflammatory fever may be considered as a salutary effort, by which the general powers of the constitution are brought into action, in order to assist in relieving some part of the body from a state of disease, by which the harmony of the functions, essential to health, is more or less disturbed. The fever may itself become a source of danger, when too violent, by aggravating the primary disease, or by exciting inflammation in other parts of the body; or when, from deficiency of the powers of life, the fever of reaction is too weak, the local disease is sometimes only partially removed, and passes into a chronic state: a deficient reaction is thus frequently the cause of inflammation being followed by changes of structure, such as indurations and effusions.

2. There is a form of constitution directly opposed to the sanguineous: it is chiefly characterized by weakness and irritability of the nervous system, and called the nervous temperament. This condition of the system is very obnoxious to inflammation, which, when developed, runs a much more irregular and unpropitious course than in the sanguine temperament. The constitutional symptoms of inflammation in this temperament are, as already stated, rather characterized by disturbance in the nervous system than by strongly increased vascular action, and the fever generally assumes a nervous, typhoid, or ataxic type. Another peculiarity of constitution which often accompanies the former, is a vitiated state of the blood, whose qualities have become altered, in consequence, probably, of some disorder in the functions of nutrition or sanguification. The combination of these two conditions of the system gives origin to the very worst forms of symptomatic fevers, called adynamic or putrid, in which to the most formidable nervous symptoms are united an extremely vitiated state of the secretions, and a great tendency of the blood and other fluids to rapid decomposition. There is sometimes a combination of the inflammatory and typhoid or adynamic forms of fever, exhibiting symptoms of high vascular excitement with great deficiency of nervous power; this is a complication of disease at-

tended with extreme danger, and requiring considerable tact and caution in its treatment.

The essential character of the irritability of temperament which predisposes to the preceding forms of constitutional derangement, is over-activity of the nervous system, combined with deficiency of the power of resistance. Irritability may be induced by deficiency as well as by excess of stimulus: a certain degree of stimulus is necessary to preserve the healthy tone of every living part: thus, if the retina be deprived of its natural stimulus by the long-continued exclusion of light, it becomes weak and irritable, and intolerant to that degree of light which was previously endured without inconvenience. An excess of stimulus, as in inflammation, produces exactly the same result. The stomach in the same way becomes weak and irritable by long abstinence from the use of meat and wine, and can only be brought back by slow degrees to tolerate even moderate quantities of stimulating food, as we see exemplified in convalescence after protracted acute diseases, and in all cases of long-continued starvation. When the privation of stimulus is carried beyond certain limits, instead of increased irritability, the sensibility becomes gradually weakened, until it is at last completely extinguished, and a state of torpor succeeds; the effect of long-continued over-stimulus is likewise to induce torpor, both extremes thus leading to exactly the same result. These illustrations of the opposite causes which may give rise to irritability, are susceptible of some important practical applications in the pathology of inflammatory diseases. There is no state of the constitution attended with so many complicated, obscure, and varying morbid phenomena, and so difficult to manage, as that which is characterized by either local or general irritability.

The irritability may be confined to one organ or to one function; it may be justly said that there is in every constitution some weak part more predisposed to disease than others; and this may be the result of original structure, or have been acquired by habits of life or previous disease.

In consequence of the great excitability of the nervous system in irritable habits, and want of power to sustain action, the sympathetic fever of inflammation is frequently characterized by a state of great over-excitement, followed by collapse. For example, the first effects of any serious injury or of the spontaneous development of inflammation in an irritable constitution may be a momentary state of depression, languor, or stupor. This, however, is, after a variable interval of time, succeeded by one or several paroxysms of rigor, sometimes very severe, which usher in the following train of symptoms: nausea, vomiting, and great irritability of the stomach; a dry brown tongue, parching thirst, obstinate constipation, scanty and high-coloured urine; præcordial anxiety and great restlessness; rapid pulse, either bounding or small, contracted, and irregular; burning dry heat of the skin; oppressed hur-

ried breathing with frequent sighing; flushed countenance; severe headach; contracted pupils and wild expression of the eyes; incoherence, amounting sometimes to fierce maniacal delirium requiring restraint; convulsive paroxysm, with great distortion of the features, not unlike epilepsy. This state is followed by one of considerable exhaustion, characterized by somnolency; sunk, haggard, and livid aspect of the countenance; profuse chilly and clammy sweats; small, irregular, fluttering pulse, rapid sometimes beyond reckoning; panting respiration; passive convulsions; hiccup and subsultus; coma and stertor, terminating in death.

The symptoms do not, however, always present this extreme degree of violence, nor lead so rapidly to a fatal result; they frequently assume the form of mild typhous or adynamic fever, characterized at one period by restlessness, anxiety, some headach, occasional low muttering delirium, moderate heat of skin, and frequency of pulse; the skin is covered with petechiæ, the tongue black and dry, the alvine evacuations vitiated and fetid; whilst at another period there are stupor, chilliness, slight convulsions and subsultus, and the usual symptoms of collapse. These various forms of constitutional derangement are especially distinguished by a rapid alternation of symptoms denoting contrary states of the system, and they derive their essential character, as before observed, from a state of excitement not supported by sufficient vital power to maintain and carry it through.

In this general state of morbid irritability, very slight causes of irritation give rise sometimes to the most violent constitutional disturbance, so that the general symptoms are not always proportionate to the extent of the local inflammation, nor a sure criterion of the degree of danger; the pulse may rise to 160, the heat of the skin be very high, and all the other symptoms usually indicating dangerous inflammation of some important organ, may be occasioned by only a trifling wound or furuncle, slight inflammation of the tonsils, or rheumatism of a joint. It is necessary, therefore, in forming a prognosis, not to be guided entirely by the general symptoms, but to take also into account the seat and extent of the inflammation. At other times, however, the local affection takes upon itself the impress, as it were, of the constitution; the inflammation is either exasperated and spreads rapidly, or it is partially suspended, or there is a complete cessation of vital action in the inflamed part, which becomes cold, livid, flabby, and sometimes gangrenous; these unfavourable changes have been frequently observed in extensive wounds after injuries or operations; in which cases no restoring process can be established so long as this disturbed state of the nervous function continues.

When, in the course of the salutary fever induced by common inflammation, any circumstance occurs to create severe disordered action of the nervous system, the regular

course of the fever is immediately arrested and completely changed, and a new train of symptoms, chiefly nervous, and of a more dangerous and destructive character make their appearance. This circumstance has led some pathologists to consider constitutional nervous irritation as a morbid condition of the system totally distinct from that which has received the name of fever. There appears, however, to be no good foundation for such a distinction, for the fever has merely assumed a new character, which corresponds exactly with that of the nervous, irritative, or typhoid fevers that have been frequently described by nosological writers.

The description of fevers under consideration attend some of the worst forms of inflammation, such as confluent small-pox, the malignant varieties of scarlatina and rubeola, several species of gangrenous inflammation, and especially hospital gangrene: this combination of local inflammation with constitutional typhoid symptoms is often extremely perplexing, presenting to the practitioner at the same moment the most opposite and contradictory therapeutic indications.

We have already stated that the nervous and irritative class of fevers are to be attributed either to constitutional causes, or to the seat, extent, and nature of the local inflammation. The following are some of the principal constitutional causes, which are extremely numerous:—great mental depression, arising from anxiety, grief, or the apprehension of death; exhaustion from over-exertion of mind, and particularly from excessive study and loss of sleep; or that consequent upon large evacuations, either by spontaneous hemorrhage, or copious bleeding and purging: an impure atmosphere; certain natural states of the body, such as that of pregnancy and lactation; the long continuance of organic disease, especially in the uterus, testicle, stomach, urinary bladder, or any of the large joints. One of the most common and active causes, however, is the abuse of spirituous liquors; the constitution of those who indulge to excess in the use of malt liquors, (as for instance brewers' servants,) is distinguished by a state of extreme plethora combined with nervous debility; and although apparently robust, they bear very ill the loss of blood, being soon affected with low delirium, partial convulsions, coma, and other symptoms of prostration. In habitual gin-drinkers the nervous system is so weakened by constant over-excitement, that they sink rapidly under a similar train of symptoms, from even slight inflammatory attacks. Over-activity and weakness of the nervous and vascular systems are predominant features of the constitution of infants and young children, and inflammatory symptoms rapidly attain in them a high degree of intensity, which is soon followed by an opposite state of collapse and sinking.

Individuals endowed with great nervous irritability, and particularly puerperal women, are sometimes subject to sudden attacks of acute pain in the head, chest, or abdomen, accom-

panied with considerable constitutional disturbance, bearing so strong a resemblance in several of its symptoms to active inflammation, that the affection has often been mistaken for either arachnitis, pleurisy, or peritonitis; it is a form of disease depending, however, entirely on nervous irritation, combined at times with some degree of active congestion. The disease sets in with rigor, generally more severe and lasting than in cases of inflammation; the reaction is proportionally violent and characterized by considerable nervous disorder and great irregularity in the course of the symptoms; there are frequent alternations from one extreme to another, differing in this respect from inflammatory reaction, which pursues its course more steadily. The general symptoms correspond with the description already given of the nervous and irritative forms of sympathetic fever, but it may be useful to offer a few observations on the local symptoms, for the purpose of defining more accurately the diagnosis of this affection from true inflammation, as it is sometimes rather obscure.

The affection of the head is characterized by acute general pain, great intolerance of light and sound, contraction of the pupils, vertigo, wakefulness, and delirium, sometimes even maniacal. This differs from arachnitis by the disease coming on more suddenly without any premonitory symptoms, and acquiring at once an extreme degree of violence; besides, in the latter the symptoms are less acute, and increase only gradually.

When the chest is affected, there is acute pain in some part, so severe as to check a deep inspiration; but the pain shifts its situation, shooting from one side to another, or towards the back; and if the patient be made to repeat the inspiration several times, the increase of pain becomes less and less; there is no cough or crepitus in making a deep inspiration, and the absence of all the signs of inflammation usually detected by the stethoscope will afford every information that can be desired for a correct diagnosis. There are, sometimes, severe attacks of palpitation and violent throbbing of the carotids, abdominal aorta, and all the large arteries.

The affection of the abdomen is denoted by acute pain and great tenderness on pressure, either confined to one part, or more or less diffused. There is as great an intolerance of pressure in some cases as exists in peritonitis, the more local pain resembling that of gall-stones. The distinction, however, from inflammation is established by the suddenness of the attack, the violence and irregularity of the general symptoms, and the severe sympathetic affection of the head, which very seldom occurs in peritonitis or enteritis.

The effects of the treatment will afford additional sources of diagnosis. The loss of blood is not well tolerated in this form of disease, depletion to a few ounces causing syncope; whilst, in the inflammatory affections alluded to, the patient can bear the abstraction of forty or fifty ounces of blood before fainting is in-

duced. Bleeding may sometimes appear to afford complete relief at the moment in cases of nervous irritation; but the paroxysm of pain soon recurs with equal if not greater violence; and it has persisted in some instances with unabated or increasing urgency, notwithstanding an enormous loss of blood. The symptoms on the other hand gradually yield to the use of purgatives and opiates, and of a light nutritive diet. In patients who have died of this affection no traces of inflammation have been discovered in any part of the body, and no other morbid appearance than at times a slight vascular injection of some of the organs.

This important form of disease had not been hitherto well understood; the profession is indebted for a good account of it to Dr. Gooch, and more especially to Dr. M. Hall.* It is attributed by the latter gentleman to intestinal irritation. This, no doubt, is very frequently the case, but we have traced it also to uterine irritation; and it may in some instances be referred to primary irritation of the brain, particularly in persons reduced to a state of great nervous exhaustion by any of the causes already mentioned. When excessive loss of blood by hemorrhage or bloodletting does not prove fatal through immediate sinking, it is sometimes followed by an excessive reaction resembling that we have just been considering, excepting only that the principal local affection is confined to the head, and there is a more marked tendency to subsequent exhaustion. We must refer for an excellent account of this latter affection to the article BLOODLETTING.

When inflammation occurs in constitutions in which an artificial plethora has been created by indulgence in the pleasures of the table, so that the functions of the different organs are oppressed by excessive repletion, the constitutional reaction is sometimes very feeble, the secretions are generally unhealthy, and the fever may assume a typhoid or adynamic character in consequence of this state of *indirect* debility. It is highly important to discriminate between a fever thus induced, and one of exactly the same character originating in *direct* weakness and nervous irritability. In the former case the debility being *indirect*, and the effect only of the oppression of the powers of life, the fever would be aggravated by the stimulating plan of treatment which in the latter case it may sometimes require; while, by disregarding the apparent debility, and having recourse to depletion and other active remedies, all the untoward symptoms are speedily removed, the character of the fever is transformed from typhoid to inflammatory, and both the local and constitutional affection pursue a more favourable course. It is in such cases that the pulse is found to acquire a greater degree of fulness, firmness, and regularity, under the repeated use of the lancet and the free exhibition of purgatives.

It was stated that the character of the constitutional symptoms was sometimes influenced by the *seat*, *extent*, and *form* of the local disease, independent of any predisposition of the constitution. Thus, with regard to *texture*, injuries of parts of little sensibility and low organization frequently induce a higher and more alarming degree of nervous irritation, than that of parts more largely endowed with nerves and bloodvessels; inflammation of the dense unyielding texture of tendons, ligaments, fasciæ, and fibrous membranes, especially of the periosteum, has already been mentioned as exciting an intense degree of local pain and tension. This generally gives rise to considerable disorder in the functions of the nervous system, while the constitutional excitement induced by the inflammation of mucous and serous membranes, or even of vital organs, more generally assumes the form of simple inflammatory fever.

The lesions of muscular and fibrous tissue, especially when the irritation is kept up by the presence of any extraneous body, are attended with a most severe degree of general irritation frequently ending in tetanus. Injuries or erysipelatos inflammation of the integuments of the head, chest, and abdomen, are followed by greater constitutional disturbance than those of other regions of the body, in consequence probably of contiguous sympathy. The inflammation of veins, which bear some analogy in their structure to fibrous membranes, is particularly characterised by symptoms of nervous and typhoid fever, and spreads rapidly along those vessels to a considerable distance. The injuries of nerves bring on most alarming symptoms of general irritation, being a frequent cause of convulsions and tetanus: this is chiefly owing to the propagation of morbid impressions along their branches, as they are rarely found inflamed. The ganglia of the great sympathetic form perhaps an exception, having been found by Mr. Swan intensely injected in cases in which the system had been strongly impregnated with mercury.*

With regard to the *form* of the local injury narrow and punctured are followed by more constitutional disorder than broad and open wounds: this frequently happens after the injury of some fibrous membrane or the puncture of a nervous filament, the complete division of which would have been of no importance. When the inflammation extends beneath a fibrous membrane, and suppuration takes place, the form of the wound not admitting of the discharge of the accumulated fluids, a considerable degree of tension and pain is the inevitable result. There may be for a time no local symptoms of the existence of the disease beyond a slight degree of tension and tenderness. When matter, however, is formed, a uniform diffused œdematous swelling, with ery-

* Commentaries on the Diseases of Females, by Marshall Hall, M.D., &c.; and Morbid and Curative Effects of Bloodletting, by the same author.

* Travers, Inquiry concerning Constitutional Irritation.

sipelatous inflammation of the skin, is observed round the margin of the wound, but without any distinct fluctuation; and this is accompanied with very violent constitutional disturbance, which can only be relieved by large and free incisions. The symptoms arising from the puncture of a nerve are more developed in the course of the nerve, and in the constitution generally than in the wound itself.

Contused and lacerated wounds, especially when of considerable magnitude, and attended with great destruction of parts, are necessarily followed by most serious and alarming derangement of the constitution. This is the case with gun-shot wounds, especially when important organs are injured and foreign substances remain within the wound; from the exposure also of muscles by the tearing away large flaps of skin; the denuding of an extensive surface of the cutis by burns and scalds; the extensive laceration, exposure, and crushing or comminution of the larger joints; the displacement and protrusion of the ends of fractured bones, with partial or complete divisions of great muscles and blood-vessels. There is considerable danger in these cases of the powers of the constitution sinking rapidly under the shock they have received, as will be mentioned hereafter; but a fatal termination may likewise take place from the violence of the nervous irritation leading to convulsions and tetanus; or from the gradual exhaustion induced by the erysipelatous, gangrenous, and sloughing inflammation which usually precedes the reparatory process in all such extensive injuries.

The constitutional symptoms are also frequently characterized by great nervous irritability and depression, low delirium, and convulsions, after severe operations, either for recent injuries or the removal of chronic diseases. Hence the great importance, whenever practicable, of attending carefully to the state of the patient's constitution previous to the performance of any serious operation.

Besides the seat, extent, and form of the injury, the nature of the exciting cause has also a powerful influence over the character of the general symptoms. This is particularly evident in the case of poisoned wounds, whether received in dissection, or from the bites of venomous animals. We have, in this class of cases, very striking and instructive examples of the most dangerous forms of constitutional affection from local disease.

The constitutional symptoms correspond with the description already given of the irritative and typhoid forms of fever, varying only in different individuals as to the relative degrees of reaction and collapse, to the combinations of severe nervous symptoms, with weak or strong vascular action, and to the more or less vitiated state of the secretions. In a case described by Dr. Duncan there was profuse dark-coloured clammy sweat of intolerable fetid and disagreeable smell, so abundant as to wet the bed-clothes and stain them of a dark colour. This diaphoresis was

critical, and it scarcely ever occurs but in cases that recover.

There are considerable differences, however, with respect to the local affection. In some cases the poisoned wound is exempt from external inflammation, the patient sinking exclusively from the action of the morbid matter on the constitution; sometimes there is the formation of a vesicle or pustule on the wound, followed by pain and inflammation of the cellular membrane of the arm, axilla, and thorax of the same side; or without any reaction in the wound, there may be severe pain and diffused swelling in the axilla and breast on the wounded side, followed by patches of a red diffused swelling and excruciating pain in distant parts of the body. In other cases there is violent reaction in the wound, leading to suppuration and gangrene in the tendinous sheaths of the finger or hand, accompanied with painful diffused erysipelatous swelling of the arm, axilla, and integuments covering that side of the body. Sometimes numerous vesicles, some of a considerable size, have formed on the inflamed parts, containing either a transparent serum or a dark-coloured fluid, the erysipelas round these vesicles assuming a dusky hue; and, lastly, the diffused inflammation of the cellular membrane on the arm or trunk has, in some instances, terminated in extensive suppuration and sloughing. The remarkable disposition shewn by the inflammation in all these cases to rapid extension, arises, no doubt, from its affecting tissues in which inflammation generally spreads by continuity, such as the absorbents, veins, subcutaneous cellular membrane of tendons, and fasciæ of muscles.* This is also owing in some measure to the erysipelatous character of the inflammation, which induced Dr. Good to give it in his nosology the name of *erythema anatomicum*.

The constitutional symptoms are chiefly to be ascribed to the introduction of the poison into the mass of the blood, whose qualities it vitiates and renders deleterious, and to the morbid action of this deteriorated blood on every part of the animal economy, and more especially on the vital organs; poisons have also been conceived to affect the nervous system in a more direct manner by the transmission of morbid impressions along the nerves. We have already stated that there are strong arguments and facts in support of each of these opinions, and that it is probable that the influence of both causes must to a certain extent be admitted.

It has been remarked that the constitutional affection is often as severe, and proves as rapidly fatal, in cases attended with scarcely any local affection, as in those in which whole regions of the body are engaged in inflammation. Extensive local disease is not therefore always so serious an aggravation as might at first be supposed; the danger is in propor-

* See Travers, Inquiry concerning Constitutional Irritation.

tion to the degree in which the poison has been mixed with the blood and has deteriorated its qualities, and to its paralyzing influence on the nervous power. It is generally considered that whenever the action of the poison can be confined either to the wounded or to any of the other inflamed parts of the body, by exciting in them inflammation of a healthy character, its pernicious influence on the constitution is considerably lessened, if not altogether prevented. Mr. Travers very justly observes, "Inflammation is not necessary to the most virulent and fatal action of the poison, and in general I should be disposed to say of these cases that the symptoms of local inflammation and constitutional irritation exist in an inverse ratio of severity."

A great many interesting cases illustrating the different forms of local and constitutional affection produced by poisoned wounds, are to be found in Mr. Travers' Inquiry concerning Constitutional Irritation—a work the most complete and valuable without exception yet published on the highly important subject of which it treats, and reflecting the greatest credit on the author's talent and observation.

The form of disease the most analogous to the preceding is that arising from the bite of the more venomous serpents, and especially of the rattle-snake (*crotalus horridus*, Lin.), and of the cobra di capello (*colubernaia*, Lin.); it only destroys life in a shorter time. The local and constitutional symptoms take place nearly simultaneously; the bitten limb swells instantaneously, and the inflammation shoots with great speed up its entire length to the axilla and shoulder; and if life continue long enough, it darts down the side over the pectoral muscle, and produces there the same kind of erythema as in the cases already described. The vital principle, however, is from the first suddenly exhausted, as if by a stroke of lightning; the blood ceases to flow in the smaller vessels of the swollen part, which feels deadly cold; the action of the heart is so weak that the pulse is scarcely perceptible; the stomach so irritable that nothing can be retained in it; dejection and horror overpower the mind, and the patient sinks with a low muttering delirium. Very powerful stimulants applied instantly may check the deadly influence of the poison, and sometimes produce a cure; but if life be sustained until the venom has exhausted its malignity, the debility is usually so extreme, and the sphacelus so extensive, that the unhappy sufferer often falls a victim to the local mischief. Dr. Mason Good, from whose Nosology the foregoing description is taken, gives an interesting account of the case of a man who died in St. George's Hospital, from the bite of a rattle-snake exhibited in London; he remarks that all other serpents have an immunity against each other's bite; but the rattle-snake not only kills every other, and even its own kind, but being so far

irritated as to inflict a personal wound has been found to kill itself.

The frightful assemblage of symptoms that characterize hydrophobia afford an example of the highest conceivable degree of over-excitement, and fatal disorder of the whole animal economy. One very remarkable circumstance connected with the action of the rabid virus is the great length of time during which it has in some cases remained dormant in the constitution before taking effect; it is difficult to account for this long period of incubation of a virus that proves so rapidly destructive after it begins to operate. The invasion of the constitutional symptoms is sometimes accompanied with slight pain and inflammation of the wounded part; but the local affection is never severe, and in some cases completely wanting.

In all the preceding cases there have been very few traces of disease found after death, beyond those resulting from the local inflammation; the only morbid appearances ever observed have been partial vascular injections in some of the internal organs, and this only in a small proportion of cases. A high degree of injection of the medulla oblongata and pharynx is stated to have been found in some cases of hydrophobia.

3. The third modification of the constitutional derangement induced by local irritation or inflammation in the irritable temperament, is that of sinking without reaction. The symptoms of this state of sinking are not unlike those of a prolonged fit of syncope, only more severe. The patient first experiences a degree of vertigo followed more or less quickly by gradual loss of consciousness. This, however, is sometimes only partial, there being rather a tendency to drowsiness, from which the patient can be momentarily roused by any strong and sudden impression; he is also affected with a sensation of shuddering, considerable degree of universal pallor, contraction and coldness of the surface, and particularly of the countenance; the pupils are dilated; the breathing is short, at one time almost imperceptible and only carried on by the diaphragm, or at another interrupted by short irregular sighing; the pulse is slow, feeble, or indistinct; the tongue and fauces are dry, the stomach is irritable, and vomiting sometimes procures relief by creating a general reaction. When, however, this is not the case, other more formidable symptoms make their appearance; the pallidness, collapse of the countenance, and coldness of the surface, increase; the breathing becomes more oppressed, and is attended with a peculiar crepitating noise; there is restlessness, jactitation, and delirium, followed by coma, convulsions, relaxation of the sphincters, and stertorous breathing ending soon in death.

The symptoms offer, however, many variations; in some cases the patient falls so gradually into a state of apparently quiet sleep, as not to excite any suspicion of danger; but this is succeeded by stupor, and he dies with-

out any struggle. In other cases, he is affected with delirium, restlessness, and frightful convulsions. Convulsions, however, may appear without delirium or coma, the latter being of most frequent occurrence in infants. When sinking does not terminate in death, it is followed by either partial, excessive, or healthy reaction. In slight and temporary syncope, returning animation is indicated by the gradual restoration of warmth on the surface, with occasionally a gentle moisture of the skin; the breathing becomes more full and free; there is deep sighing and sometimes hysterical sobbing; the pulse recovers its fulness and strength; and consciousness gradually returns as if the patient were awaking from sleep.

In the state of more severe sinking reaction is generally ushered in by rigor: a state of great depression of the nervous energy has the effect of lowering the action of the heart, and causing a gradual accumulation of blood in the central parts of the body, while the circulation is diminished in the capillaries of the surface and extremities. This unequal distribution of the circulating fluid impedes the action of the two most important vital organs, until the constitution, unable to bear any longer the irksome oppression, is roused to a convulsive effort, in order to remove the obstacles opposed to the circulation and respiration. The commencement of this effort at reaction is indicated by rigor, and sometimes also by vomiting and hiccup; the action of the heart is immediately increased, and the reaction becoming general, leads to a restoration of the circulation and heat of the surface, to a relief of the embarrassed breathing, and to a revival of the depressed energies of the brain and nervous system. If these changes take place without violence and are sustained for some time, a permanent healthy reaction is established; they may, however, be only momentary, in consequence of the insufficiency of the nervous power to keep up reaction, and the patient sinks again into collapse. Rigor of long continuance without any return of heat, or frequently recurring, indicates likewise a want of power in the system. At other times the reaction may be too strong, and lead to a condition of the system opposite to sinking,—that of over-excitement. The shudder which accompanies shock differs from rigor: it is a cerebral affection of short duration, produced by a painful impression of the mind, and it is not necessarily connected with any change in the temperature of the body.*

It is of great practical importance that the distinction between these opposite morbid conditions of the system should be well understood, and the changes from the one state to the other require to be watched with the utmost vigilance; for the treatment which may be the means of restoring life during the period of sinking, might prove destructive during that of reaction. The rule laid down by Mr.

Travers, of maintaining action without forcing action, should be constantly borne in mind; the effect produced by stimulants must also be carefully observed, in order that they may be laid aside as soon as reaction has taken place, and opposite measures should then be adopted if required.

The state of sinking is brought on by all causes tending to depress considerably the nervous power. Nervous weakness being the chief characteristic of an irritable constitution, it is strongly predisposed to this form of disease. The effect of sudden and painful emotions on weak and irritable persons in causing syncope and convulsions is well known, and has even proved fatal in individuals much exhausted by disease. The breathing of putrid and pestilential effluvia has sometimes caused such a degree of faintness and sinking that life has been extinguished before reaction could take place. Individuals have died in the cold stage of the algid fever from a similar cause. Several powerful narcotics, by completely paralyzing the action of the brain and nerves, and probably also that of the heart, prevent all reaction, and destroy life with amazing rapidity. Patients who have been much exhausted by long and painful inflammatory affections, sometimes sink unexpectedly at the moment they were considered convalescent. Some of the cases of sudden and unexpected death that take place without any known cause during attacks of severe illness, may reasonably be accounted for in this manner. Profuse hemorrhage is a frequent cause of sinking, especially in puerperal women, whose vital powers have been much lowered by the sufferings of tedious and painful labour: the sinking in these cases is often attended with frightful convulsions. Among the frequent causes of sinking is to be reckoned the sudden shock the constitution receives from severe injuries, which operate in this way either in consequence of their extent or of the tissues that are affected; as, for instance, when many textures are implicated in a wound, and extensive portions of skin detached, or when joints and tendinous structures are lacerated, and large bones comminuted.

The effect of extensive burns in causing direct prostration is very remarkable; the great sensibility of the skin as the organ of tangible impressions, the importance of its functions as a secreting surface, and its numerous sympathies with all the vital organs, will sufficiently account for the system receiving a severe shock when it is extensively injured. The danger is greater when the burn is seated on the integuments of the trunk than on those of other parts, in consequence, probably, of contiguous sympathy. The tendency to sinking may continue for the first three days after the accident; but at the end of this period reaction is generally established. The situation of the patient is very analogous to that of a person stunned by a fall; he is in a state of apathy bordering on stupor, without actual loss of consciousness; there is an absence of all pain, as if the sensibility had shrunk

* Inquiry concerning Constitutional Irritation, by B. Travers, Esq. p. 138.

below the point of pain. The complaint of pain is, therefore, rather a favourable sign; continued shivering is completely the reverse.

The shock the brain receives in concussion brings on symptoms of sinking; the stupor resulting from other casualties is the effect only of functional disorder, while that arising from injuries of the head is generally connected with physical derangement of the organ: in the latter case, when reaction takes place, there is much greater reason to apprehend and guard against cerebral inflammation than in the former.* Children are sometimes affected with sinking after excessive evacuations; this is chiefly indicated by a tendency to stupor and coma, which has often been mistaken for hydrocephalus. Full details respecting the diagnosis and treatment of this important affection will be found in the article *HYDROCEPHALUS*. The shock inflicted by the pain of a severe operation often brings on sinking, especially if the vital powers have been previously depressed by recent injury or painful chronic disease, or else if the patient has been under great dread of the operation, or much alarmed at the prospect of death.

Severe and intense pain is of itself destructive. Puerperal women have sunk after difficult and protracted labour, from the mere paralyzing effect of intense and long-continued pain; ruptures of the stomach, gall, and urinary bladders are sometimes productive of such sudden and excruciating pain as to bring on rapid and fatal syncope. The effects of severe pain are variable: the sudden infliction of intense pain may be instantly followed by such a degree of direct general torpor that the individual appears as if completely stunned, and little or no pain is afterwards experienced. When intense pain is long endured, it absorbs every other feeling, and induces a remarkable degree of insensibility to all surrounding impressions. Severe pain at other times brings on delirium, convulsions, vomiting, suspension of the secretion of urine, and other symptoms of over-excitement; but this is of short duration, and is soon succeeded by a state of exhaustion and torpor. Long-continued pain impairs all the operations of life, and gradually exhausts the vital principle itself; so that pain has been justly called the greatest sedative in nature. The sudden remission of intense pain has sometimes been followed by syncope and death.

Very intense pain of an unimportant part is sometimes well tolerated; while slight pain of a vital organ or highly sensitive part, such, for instance, as the urethra, may be sufficient to cause syncope. The constitution in some cases becomes accustomed to the impression of moderate pain, when frequently repeated or long-continued; the susceptibility to all impressions, whether pleasurable or painful, being lessened by habit. When the pain of inflammation is so intense as to constitute its most prominent symptom, and has not yielded to full depletion, the in-

flammation is sometimes kept up by the continuance solely of the pain. It is of great importance in such cases to subdue the pain at once by means of large opiates; we have seen attacks of peritonitis attended with violent pain yield immediately to this plan of treatment.

We shall conclude this short account of the various acute forms of constitutional derangement that are induced by inflammation, with the following concise and at the same time comprehensive remarks of the great Hunter:—"Nature requires to feel the injury; for where, after a considerable operation, there is rather a weak, quiet pulse, often with a nervous oppression, with a seeming difficulty of breathing, and loathing of food, the patient is in a dangerous way. Fever shews power of resistance; the other symptoms shew weakness sinking under injury."*

Local inflammation may go through its different stages without any interruption, except a certain degree of exacerbation and remission in its symptoms at different periods of the twenty-four hours. But inflammation is also sometimes intermittent, and even periodical, and the constitutional symptoms in these cases follow the order of the local symptoms. There is a greater tendency to periodicity and intermission whenever the nervous system is much affected.

The order in which the constitutional symptoms occur with respect to the local symptoms is variable. In some instances they precede the local, as in the whole class of exanthematous diseases, and often also in erysipelas. In most inflammatory affections arising from external injury, the febrile symptoms succeed to the local at a longer or shorter interval of time, according to the seat and severity of the injury, and the susceptibility of the constitution. In some very severe injuries, as for instance in extensive burns, the local and constitutional symptoms appear almost simultaneously; the same is often observed in severe inflammation of the pleura and peritoneum.

There are also differences between the local and constitutional symptoms with respect to their relative degree of violence. The febrile symptoms, as before observed, run sometimes so high that they completely conceal the local affection; and they may assume so formidable an appearance, either from their violence or malignity, as to constitute the chief source of danger. Inflammation is sometimes excited in distant organs by sympathy with the organ first affected, and the secondary inflammation becomes stronger than the primary, so as to completely supersede it; in which case a new disease is established. If, however, inflammation proceeds in two organs at the same time, the additional disease, although even slight, increases considerably the danger, particularly if the constitution has been much impaired by the first inflammation.

The organs the most subject to be affected

* For a full account of the phenomena of shock, &c. see Travers, *op. cit.*

* Treatise on the Blood and Inflammation, ch. iv. s. 6.

with sympathetic inflammation are the brain, the lungs, the alimentary canal, and sometimes the skin. There are often more severe sympathetic pains in other organs than in the inflamed one, these pains being chiefly of a nervous character: this is particularly the case in inflammations of the mucous membrane of the alimentary canal and urinary bladder, and also in nephritis. Gastro-enteritis is frequently attended with severe pain in the head and loins, or violent cramps and pains in the lower extremities, while very little pain is felt in the stomach and bowels: this accounts for the original disease in these cases being so frequently overlooked. Severe pain in the stomach is one of the common symptoms of nephritis. There is a remarkable tendency in some varieties of inflammation to change frequently their position through the influence of sympathies; this peculiarity is frequently observed in erysipelas and rheumatism, and in the inflammation of the parotids called *mumps*, which is often superseded by inflammation of another organ, as the brain, the testis, or mamma. This erratic tendency of inflammation will be more fully considered when treating of metastasis.

Idiopathic, or essential, and symptomatic fever have been considered by some pathologists as differing materially in their nature. There does not, however, appear to be any reasonable ground for this distinction. Inflammation is frequently the exciting cause of fever; but, on the other hand, inflammation often occurs in the course or towards the decline of fever as one of its consequences. The primary morbid phenomena essential to the existence of fever—a disturbance in the functions of the heart, the brain, and the stomach—are always the same, whether arising from a deteriorated state of the blood, from external morbid impressions acting on the brain and nervous system, or from sympathy with a diseased organ. These exciting causes may possess different degrees of activity, create a greater disturbance in one order of functions than in the others, and be single or combined in the same case; and hence the variations observed in the character, severity, and course of the symptoms by which the different types of fever are distinguished. When an inflamed organ is the exciting cause, the fever subsides as soon as the inflammation is subdued. When a vitiated state of the blood is the cause, the fever likewise subsides as soon as the blood has recovered its healthy qualities. When both these causes are combined in the same case, although the local inflammation may be quickly removed, the fever pursues its course until the blood also is restored to its healthy condition. We have in each of these cases the same primary morbid phenomena, differing only in degree, and in being variously combined according to the nature, activity, and combinations of the exciting causes.

Before concluding our remarks on the different forms of symptomatic fever, we have to notice some peculiarities in the state of the pulse and in several of the other symptoms, deserving of attention. The character of the

pulse varies not only with the intensity of the inflammation and type of the fever, but also according to the particular organ or structure affected. The pulse of common acute inflammation is generally characterized by fullness, hardness, and moderately increased frequency. In the inflammation, however, of some of the abdominal viscera, such as the stomach and intestines, the pulse is small, contracted, wiry, and rapid; there is also a remarkable degree of sinking and general prostration of strength, the consequence probably of the extensive sympathies of these organs with the brain and spinal marrow, through the medium of the ganglionic nerves. These two peculiarities in the symptoms might possibly mislead, if not well understood, with respect to the true nature of the complaint, and prevent the adoption of those active measures by which alone the patient can be saved; the usual effect of free depletion in these cases is to increase the fullness and strength of the pulse; this variety of the pulse has been called *abdominal*, as it is seldom observed in inflammation of the organs of other cavities; it does not either attend the inflammatory affections of all the abdominal viscera, but more particularly the inflammations of the digestive tube, especially when seated in the peritoneal coat and various prolongations of that membrane.

The character of the pulse is likewise influenced by the particular structure affected. In the inflammation of serous and fibrous membranes, and in most cases of inflammation attended with intense pain, the pulse is in general contracted, hard, wiry, and very frequent; whilst in inflammations of the cellular tissue, of mucous membranes, and of parenchymatous and glandular organs, the pulse is usually fuller softer, and less rapid; in diarrhoea the pulse, as is well known, is sometimes intermittent. The frequency of the pulse, instead of being increased, may be reduced below the standard of health, notwithstanding the existence of severe and dangerous inflammation; this arises generally from some affection of the brain, lessening the general susceptibility of the system, and preventing the free development of the constitutional symptoms. In the inflammation of muscular and fibrous tissues, there is a very high degree of heat, and great frequency of pulse, followed by profuse and long-continued perspirations; the degree of danger, therefore, as before stated, is not always in proportion to the severity of the general symptoms.

We have hitherto been considering the various forms of constitutional affection arising from *acute* inflammation. We have next to describe the constitutional derangement that attends *chronic* inflammatory diseases, and which differ from the preceding in several points of considerable importance.

Constitutional symptoms of chronic inflammation.—The term chronic inflammation implies the absence of acuteness and activity, and a tendency to long continuance. Inflammation may be of a mild and obscure character from the beginning, or else it may have been acute

at first, and have subsequently assumed a mild and *chronic* form. If after acute inflammation has reached its height, it is not brought to a speedy termination, or is only partially removed, it has a great tendency to become chronic. Both the local and general symptoms of chronic inflammation differ in several respects from those of acute, and require also some important modifications in the mode of treatment. We shall first briefly consider the principal differences observed in the local symptoms, as they will assist in explaining the modifications of the constitutional symptoms.

The local symptoms are never so strongly marked, and are sometimes, indeed, so obscure as to be perceptible only to the scrutinizing eye of an experienced observer; there is but a very slight degree of pain, seldom much heat or redness, and sometimes but little swelling. The functions of the inflamed organ are more or less disturbed; in some cases the functional derangement is remarkably slight, notwithstanding the existence of extensive organic disease; the secretion of bile has often continued healthy in livers considerably enlarged and thickly studded with tubercles; the respiratory function has not been very sensibly affected, although a vast abscess has been found in one of the lungs. When the progress of the inflammation has been very slow and circumscribed, so that the remaining portions of the organ have preserved their healthy condition, and the constitution has been able to adapt itself gradually to its diminished activity, the local affection is not aggravated by any strong general re-action.

Mild cases of chronic inflammation excite very little general disturbance; this is sometimes limited to a slight loss of flesh and decrease of the general strength, and is also characterized in some cases by a change in the colour of the skin, which becomes either pale or sallow. The severer cases are attended with various degrees of febrile excitement, never amounting to the regular continued fever of acute inflammation, but occurring in paroxysms with variable intervals of more or less complete remission. During the latter part of the day, or first hour of the night, the patient experiences a sensation of general uneasiness, languor, and sometimes chilliness, followed by headach, frequency of pulse, heat of skin, dryness of the mouth, and thirst; these symptoms continue until morning, when they subside either with or without perspiration. There are frequently conjoined with the preceding, a variety of nervous symptoms, especially in chronic inflammation of the liver and uterus; and the local affection not being detected, the disease has been often treated as purely nervous. When the disease lasts for any considerable time, the general health becomes materially impaired; the patient is affected with progressive emaciation, or sometimes partial dropsy, and dies in a state of marasmus. If the inflammation leads to suppuration, symptoms of regular hectic fever make their appearance.

The progress of chronic inflammation is

generally marked by many variations, the symptoms being at one time slow and obscure, or to all appearance so completely removed as to excite hopes of recovery, and increasing suddenly at another time without apparent cause. Chronic inflammation is prolonged in some cases by a frequent repetition of the exciting causes, such as irregularities of diet, exposure to cold, &c., or its continuance may depend on the weak and irritable state of the constitution. One circumstance important to be remembered, is the strong tendency of chronic inflammation to assume an acute form, from the influence of even very slight causes. This passage of chronic into acute inflammation is generally attended with considerable danger; for an organ of which the structure has been previously weakened or perhaps materially altered, is little able to resist the effects of acute disease. Sometimes, however, the supervention of acute inflammation has been the means of removing chronic disease of long standing, as is often the case with chronic sores and swellings.

Chronic inflammation has, in some cases, been quickly removed on the sudden appearance of some other more general affection, such as a cutaneous eruption, rheumatism, gout, &c.; it seldom terminates in gangrene, but most frequently in the thickening and induration of textures, the formation of false membranes; or in adhesions, ulceration, sero-purulent effusions, ossification, or the formation of new tissues. When acute inflammation is on the decline, the danger of rousing anew excessive action by the premature exhibition of stimulating diet or medicines is generally understood; there is, however, another risk at this period which is not unfrequently overlooked. When the strength of the patient has been reduced beyond a certain point, by too long a perseverance in the use of active remedies and of low diet, there may not be sufficient power for the establishment of the restorative process, and the inflammation may assume from this cause a chronic and unhealthy character; this is particularly liable to occur in old or weakened subjects. The study of this class of inflammations is of considerable importance, and a great deal of valuable information on the subject will be found in the works of Pujol and Broussais.*

Progress and duration of inflammation.—The progress of inflammation, with respect to its more or less favourable course, is influenced by the structure, situation, and state of the part affected, by temperament, hereditary disposition, diathesis, age, sex, habits of life, quality of the air, climate, &c. We shall offer a few remarks on the influence of each of these circumstances.

It is observed, with respect to *structure*, that in highly organized and vascular parts, in those in which the circulation is vigorous from their vicinity to the heart, and endowed with a strong nervous energy, inflammation is generally more disposed to run a speedy and favourable course, than in parts of an opposite

* *Histoire des Phlegmasies Chroniques.*

structure, or more remote from the centre of the circulation. Hence inflammation of the skin, cellular tissue, and muscles goes more rapidly through its different stages, whatever be its termination, than the same affection in bones, tendons, fasciæ, and ligaments; when parts possessing a low vitality are preternaturally excited, they frequently mortify, not having sufficient power to resist the disturbance of the inflammatory action. The lower parts of the body are, for the above reasons, more prone to inflammation, and when inflamed recover more slowly than the superior parts; a depending position retards also the curative process by impeding the return of the blood through the veins. The inflammation of vital organs, although they are very vascular, often takes an unfavourable course, on account of their extensive sympathies giving rise to severe constitutional reaction.

One of the remarkable and important laws of healthy inflammation is that of its being always most actively developed on the side of the part affected which is nearest to the external surface, or to some outlet: this is beautifully exemplified in the pointing of abscesses; if seated under the skin, or in the muscles, the walls of the abscess become thinned by absorption on the side nearest the skin, and the pus tends to make its way to the surface; or if seated near the intestines, the pointing takes place towards the cavity of the bowel. It is thus that foreign substances are sometimes cast off, after remaining even for years lodged in some parts of the body,—a passage being gradually made by the spontaneous development of inflammation on that side of the substance only which is nearest the surface.

With regard to the *state* of the part, whenever it has been previously weakened by inflammation, it is more predisposed to a return of disease, and each attack lessens the chance of a complete and permanent recovery; thus persons who have suffered from severe injuries of the head are sometimes rendered delirious by stimulating food, or taking the smallest quantity of any spirituous liquor. When the circulation of a part has become languid, in consequence of the ossification of its vessels or of paralysis, there is not sufficient power for the perfect development of the inflammatory process, and it often terminates in mortification. All new formed parts, such as encysted or sarcomatous tumours, excrescences, granulations, cicatrices, false membranes, callus, &c. having only a low degree of vitality, cannot long resist inflammatory action, and are soon destroyed either by ulceration or sloughing.

We have already adverted to the influence of *temperament* over the constitutional symptoms; the local character of inflammation is also considerably modified by diversities of temperament: thus the sanguine temperament is predisposed to acute inflammation of highly vascular organs; the bilious temperament to erysipelas, &c.

Inflammation is greatly modified also by the *diatheses*, or morbid predispositions, and in many cases these morbid states of the constitu-

tion give the inflammation a specific character: thus the scrofulous, rheumatic, and gouty diatheses, whether natural or acquired, give origin to as many corresponding varieties of inflammation, as will be more particularly specified hereafter. Many peculiarities of constitution are transmitted from parents to their progeny; these hereditary morbid tendencies are likely to be brought into action, if the individuals be placed in circumstances favourable to the development of the diseases which they induce; otherwise they may long remain dormant in the constitution, and sometimes even, after passing over one or two generations without manifesting themselves, may break out in the third.

The progress of inflammation is materially affected by *age*, in consequence of the changes in the activity of the circulation and distribution of blood, and in the energy of the nervous system observed at the different periods of life. In *childhood*, the circulation being very active, the inflammatory process is always rapid and mostly healthful; but the great determination of blood to the head, peculiar to that age, occasions a more than ordinary tendency to inflammatory affections of the brain and other parts about the head, such as hydrocephalus, ophthalmia, otitis; to mumps, and other glandular swellings of the neck; to cyanche, cutaneous eruptions of the scalp, &c. The inflammatory affections of children are frequently attended with convulsions, owing to the great susceptibility of their nervous system. Another peculiarity by which these affections are distinguished is their remarkable disposition to assume either a remittent or intermittent form; this may perhaps be also attributed to the irritability and weakness of the nervous system in childhood. In *youth*, the progress of inflammation is still more vigorous and healthful, but the tendency to affections of the head diminishes, and the thoracic viscera become more prone to inflammation; accordingly pneumonia, pleurisy, and phlegmonous inflammation, are observed to prevail at that age. In the *adult* period of life, inflammatory action appears more particularly directed towards the abdominal viscera, giving rise to attacks of gastritis, enteritis, hepatitis, nephritis, cystitis, &c. In *old age*, as the powers of life decline, the energy of the vascular system becomes weakened, and its organization is frequently impaired; the inflammatory action is therefore much more languid, and less disposed to terminate favourably; this unpropitious tendency is often increased by the pre-existence of visceral disease. This period of life is also characterized by weakness and irritability of the nervous system. The most common inflammatory affections of old people are chronic catarrh, peripneumonia-notha, chronic cutaneous eruptions, gangrenous erysipelas, &c.

The influence of *sex* is to be considered. The greater delicacy of fibre and higher degree of nervous susceptibility of females, predisposes them more to inflammation than men; although this is in some measure counterbalanced by males being more exposed to the influence of

the exciting causes from the nature of their pursuits and their irregular habits of life. The course of inflammation in women is more rapid and less steady than in men, being complicated with many nervous symptoms: their inflammatory affections are also greatly modified by the influence of the uterine functions.

The *habits and condition of life* are likewise deserving of some consideration. In persons of sedentary habits, or who indulge in food and liquor to excess, inflammation is generally severe, and often assumes an unhealthy character, in consequence of the repletion of the system and vitiated condition of the fluids. When the body has been much debilitated by a deficiency or the bad quality of the food, previous disease, or any other cause of weakness, the inflammation is languid, and there is not sufficient power to establish any reparatory process; hence the great difficulty often experienced in such cases in obtaining the reunion of fractured bones, the healing of ulcers, or resolution of tumours, &c. There are also peculiar forms of inflammation induced by particular employments; as, for instance, the chimney-sweepers' cancer, the bakers' and grocers' itch, the barrel-grinders' cough, &c. an excellent account of which will be found in the article *ARTISANS, DISEASES OF*.

The effects of *air* on the progress of inflammation are very remarkable, and entitled to particular attention. They are to be attributed chiefly to the important influence of the air over the qualities of the blood and vigour of the circulation. A pure air imparts to the blood rich and nutritive properties, and acts as a stimulus to the circulation, so that wholesome materials are supplied, by which the inflammatory processes are carried on with activity to a favourable termination; in an impure and foul air, the blood is impoverished or vitiated, the circulation feeble or irregular, and all the morbid actions necessarily partake of this deficiency of power. The air exerts moreover a powerful and direct influence over the nervous system, and through it on all the functions of life, especially those of the digestive organs, and of the skin. These reasons sufficiently account for the slow progress of inflammation, and the unhealthy character it so frequently assumes in close ill-ventilated apartments, low situations, cold and damp seasons, or during the prevalence of certain winds; and likewise for the remarkable improvement observed after the removal of patients to a more airy situation, by transferring them even from a lower to an upper floor in the same building, and after favourable changes of weather. It has been justly remarked by Mr. James,* that there is no poison more injurious than foul air, and no restorative more effectual than pure air; indeed it exercises in this respect a greater influence than even food. The effects of the damp and foul air of ill-ventilated wards in causing the disease called hospital gangrene, have been frequently noticed by practical writers.

Besides these general effects of air, there are certain regular and periodical changes produced in the human constitution by the different seasons, which considerably modify the character and course of inflammation; these changes seem to depend partly on the circumstance of each season causing a greater determination of blood towards certain organs than others. We thus see inflammatory diseases most prevalent during winter and spring: pneumonia, inflammatory catarrh, and acute rheumatism are principally diseases of winter: pleuritis, cerebral inflammation, the febrile exanthemata, and other acute diseases of the skin, are the general concomitant affections of spring. In summer and autumn there appears to be less predisposition to very acute inflammation, and the predominant diseases of these seasons are congestions and sub-acute inflammations of the liver and mucous membranes of the alimentary canal, such as bilious fever, gastro-enteritis, dysentery, diarrhoea, and cholera morbus. During the prevalence also of epidemic diseases all local inflammations are observed to partake more or less of the type of these diseases. If it be inflammatory, the local diseases are very acute; if typhoid, the local inflammation is of a low type. Some epidemics create a remarkable tendency to erysipelatos inflammation, and when the epidemic has either a remittent or intermittent type, the most common inflammations show a remarkable tendency to assume the same character. This influence of epidemic constitutions over local diseases has been well described by some of the ancients, and especially by Sydenham and Stoll.

The *duration* of inflammation varies according to its intensity, the texture of the part affected, nature of the exciting cause, and state of the constitution. Violent inflammation is seldom of long duration; it may exist for only a few hours, and has sometimes proved fatal in the course of a day; it passes through its different stages with great rapidity in infants, who require on that account to be visited frequently when labouring under inflammatory affections, as considerable changes may take place in the course of even a few hours; it may also prove rapidly fatal when affecting vital organs, such as the heart and brain, particularly if attended with excruciating pain. When inflammation is not violent, it may last for months, and even years; this difference in duration forms the ground of one of the divisions of inflammation that will be presently examined. Inflammation, when of long continuance, frequently induces changes of structure. One of the effects of long-continued inflammation is to leave the vessels so much weakened that they remain preternaturally dilated, and the part preserves a certain degree of redness and thickening which may not disappear for years; this happens particularly in the cicatrices and scars consequent upon burns and old ulcers.

Varieties and divisions of inflammation.—The variety of forms assumed by inflammation are extremely numerous, and have been arranged under some classification or other by

* James on Inflammation, p. 80.

most practical writers. But in the present state of pathological knowledge we are too imperfectly acquainted with the exact nature of proximate causes, and with many other important circumstances relating to the history and theory of diseases, to be able to frame any truly scientific nosological arrangement, and all the classifications of inflammation are on that account more or less defective. They are deserving, however, of some notice, as tending to give a systematic view of the most important peculiarities of inflammation, and as affording some assistance in the study of this multifarious class of diseases, and in laying down general rules of practice.

Inflammation has been divided into *acute* and *chronic*: it is important that these terms should be understood as expressing only different degrees and not different kinds of inflammation. The term *acute* is generally used to denote that the inflammatory process is both active and of short duration: it may be considered sufficiently accurate in the former sense, but will often prove incorrect in the latter; for inflammation is susceptible of being maintained in a state of great activity for a considerable length of time, especially if the exciting cause continues in operation, or its application be frequently renewed. *Chronic* inflammation implies the absence of acuteness or activity, and a tendency to long duration. When acute inflammation is only imperfectly relieved, it often continues for a considerable time in a state of lessened activity, and is then chronic in every acceptance of the term; but inflammation may be of an obscure and mild character from the very beginning, and it cannot therefore be correctly called chronic from the mere absence of acuteness. An intermediate degree of inflammation between the acute and chronic has been termed *sub-acute*; this frequently consists of the state we have described by the name of congestive irritation.

Inflammation has also been divided into *active* and *passive*: these terms designate merely the degree of intensity of the inflammatory action, and are not exactly synonymous with acute and chronic; for passive inflammation may be of short duration, whilst active inflammation may, as already stated, be more prolonged. When the pain, redness, and heat are only slight, while the swelling is considerable and attended with an abundant secretion, the inflammation is said to be passive: this form of affection ought rather to be considered as a species of congestion; and the term passive can scarcely be applied with strict propriety to any species of true inflammation. Inflammation is sometimes distinguished into *tonic* and *atonic*; these terms refer more to the powers of the constitution than to the intensity of the local disease. When the constitution is strong, the inflammation is called tonic. If the constitution be in a state of debility, there may be very violent inflammation in a part; but in consequence of the want of sufficient power in the system to maintain this local action, it soon subsides; and the inflammation either disappears, as is seen in atonic gout, or perhaps

mortification takes place. This is called atonic inflammation. The terms *sthenic* and *asthenic* have also been applied to inflammation; they are derived from Dr. Brown's well known division of diseases into two great classes, and refer, like the terms tonic and atonic, to the powers of the constitution; sthenic being used to express a high degree of power, and asthenic a deficiency of power.

In order to avoid the ambiguous and ill-defined notions generally conveyed by the terms active and passive, acute and chronic, &c. as applied to inflammation, Andral has adopted a new and very simple division. He classes all inflammations and congestions under one head, termed *hyperæmia*, or excessive presence of blood in the part. When the accumulation of blood is due to increased action, this constitutes *active hyperæmia*, including all forms of active congestion and inflammation. When, on the contrary, the accumulation of blood arises from debility or obstruction, &c. it is called *passive hyperæmia*, which comprehends passive congestions. Andral's division has still, however, the disadvantage of applying the same name to diseases very dissimilar in their characters, such as, for instance, every variety of active congestion and inflammation; besides, moreover, the great inconvenience always attached to the introduction of any new nomenclature in science. It appears, therefore, more desirable to adhere to the old terms, endeavouring only to give them a more precise meaning.

Inflammation may be *continued*, *remittent*, or *intermittent*. Acute inflammation in healthy constitutions endowed with sufficient power to maintain vigorous action, assume most generally the continued form. We have already stated, in speaking of the influence of age, that the inflammatory affections of children exhibit a great tendency to remittance or intermittence; and that the same peculiarity is sometimes observed in persons of an irritable temperament or advanced in life. We have instances of intermittent inflammation in ophthalmia, which sometimes returns very violently every evening, or every other evening, at a certain hour. Otitis is frequently intermittent; and catarrh has also occasionally assumed a periodical character.*

Next to the duration and different degrees of intensity of inflammation, its causes have also been adopted as the basis of several divisions. Inflammation considered in this point of view has been distinguished into *accidental*, *spontaneous*, and *symptomatic* or secondary.

Accidental inflammations are those arising from *mechanical* causes, such as pressure, friction, cutting, and lacerating instruments, &c. or *chemical* causes, including all irritating, acrid, and corroding substances, high degrees of temperature, and great cold: all these causes excite inflammation in the part to which they are applied; but the inflammation arising from cold often manifests itself at a distance from

* Elliotson's Lectures on Inflammation, Med. Gaz. Dec. 1831.

the part on which the cold has acted. In accidental inflammations the local symptoms generally precede the constitutional, and the latter follow, with respect to their increase or decline, the course of the former.

Spontaneous or idiopathic inflammations are those which cannot be distinctly traced to the action of any external agent, and appear to derive their origin from various morbid conditions of the constitution, such as a state of general or local plethora, the over-excitement or deficient action of certain organs, &c. Spontaneous inflammations are susceptible of being influenced to a certain extent by peculiarities in the state of the atmosphere, the exact nature and mode of operation of which we are unable to explain. That such, however, is the fact is clearly proved by the circumstance of this class of inflammations assuming sometimes an epidemic form, which constitutes a good line of distinction from the preceding class.

Symptomatic or secondary inflammation.—It has already been observed, when describing the constitutional symptoms, that whilst inflammation was frequently a primary cause of great general disturbance in the animal economy, it was also on many occasions only symptomatic of a previously disordered state of the constitution; the inflammation appears then as a symptom only of another more general disease. Among the causes of symptomatic inflammations, one of the most frequent is the introduction into the system of poisons, such as those of variola, rubeola, scarlatina, &c. The patches of erysipelatous and gangrenous inflammation which appear in different and remote parts of the body after poisoned wounds, are merely symptomatic of the typhoid and malignant fever which is the primary and more immediate effect of the poison. The various cutaneous affections attending the febrile exanthemata are merely symptoms of a general disease, and do not constitute its essential features, as they are often very slight and sometimes even altogether wanting; the latter case constitutes a variety of disease described by nosologists as *variola sine variolis*, *morbilli sine morbillis*. The buboes of the plague afford another instance of symptomatic inflammation, and the various swellings and critical abscesses subsequent to continued fevers are of the same description. The paroxysms of some intermittent fevers have been attended with regular attacks of ophthalmia, diarrhoea, or dysentery. Erysipelas and anthrax are in numerous instances to be traced to a state of general repletion, combined with a vitiated condition of the blood and of all the secretions, and are accompanied by typhoid fever.

Symptomatic inflammation is of frequent occurrence also after the healing of large and long-established ulcers; after the removal of a limb, in a state of profuse suppuration in consequence of compound fracture; and particularly in cases of phlebitis, which are so often attended with the formation of abscesses in parts remote from the original inflammation. Symptomatic inflammation is

attributed in general either to nervous sympathy or to a vitiated state of the blood. The absorption of pus and its combination with the blood is considered by some pathologists as the principal cause of the secondary inflammation and suppuration. It has been ascertained beyond doubt that pus is sometimes absorbed both by the veins and lymphatics, and circulated with the blood; it may be either the produce of the inflammation of the vessels themselves, as in cases of phlebitis, or be taken up by them from inflamed and suppurating parts. Pus has been found in the veins and lymphatics in the neighbourhood of diseased joints, of unhealthy stumps, of old ulcers, and of inflamed organs, such as the uterus, intestines, liver, and brain. Collections of matter have also been found, however, in these cases, in parts of the body remote from the inflamed organ; as, for instance, in the lungs, spleen, joints, serous cavities, and even in some of the muscles; and this has occasionally taken place without the least trace of any concomitant inflammation being discovered in these parts. M. Dance states, in his work on this interesting subject, that he has observed pus in the veins of the arm, on bleeding women affected with uterine inflammation and phlegmasia dolens. We have seen purulent deposits in several parts of the spleen of a man who died of fever soon after the healing of a large chronic abscess between the muscles of the thigh; the texture of the spleen was in every other respect perfectly healthy. Small collections of pus have been observed by Andral and Velpeau in the centre of the coagula of blood found in the heart and large vessels.* It appears reasonable to conceive that the mixture of pus with the blood should become a source of irritation, as well as any other heterogeneous principle, and this may, therefore, be admitted as an occasional cause of symptomatic inflammation; it can scarcely, however, be considered as the only cause, since we have seen that these accumulations of pus sometimes take place as the effect of an ordinary process of secretion, and without any accompanying inflammation.

The absorption of pus was for a long time erroneously considered to be the primary cause of hectic fever. That this is a mistake is clearly proved by the fact that hectic fever is often induced by the long-continued irritation of vital organs, with very little or even the total absence of suppuration; while very extensive collections of matter may exist for a long time in parts of less importance without any hectic.

Symptomatic inflammation differs in most cases from spontaneous inflammation by following a fixed and regular course, and having always the same mode of termination, as is exemplified in the febrile exanthemata. Among the secondary inflammations may be included that of the pleura consequent upon the opening of a tubercle or abscess into its cavities, or that of the peritoneum from the perforation

* Andral, Pathol. Anat. transl. vol. i. p. 97.

of the intestines, bursting of an hepatic abscess, or rupture of the uterus.

The division of healthy inflammation adopted by Mr. Hunter was the adhesive, suppurative, and ulcerative. He observed that in the cellular membrane, and all circumscribed cavities, the adhesive inflammation takes place more readily; whilst in internal canals, and all cavities having a communication with the exterior, and which are lined with mucous membranes, the suppurative and ulcerative inflammation come on most readily, and the adhesive very seldom. Adhesions would in general prove hurtful in these membranes; and they only take place from very violent and long-continued inflammation.

Mr. James, in his work on inflammation, takes, as the basis of his division of inflammations, their disposition either to be limited by the effusion of organizable coagulable lymph, or to spread. This distinction appears founded in nature; for the common inflammation of the cellular membrane, and of parenchymatous and glandular organs, which is termed phlegmon, is generally circumscribed by the effusion of coagulable lymph; whilst in certain textures, such as the fibrous, inflammation shows a remarkable tendency to spread, assuming the character of erysipelas; and the same tendency seems also to be induced in all other parts of the body by a deficiency in the powers of the constitution; a certain degree of vital action being required for the production of coagulable lymph. The orders in Mr. James's division are established on the principle of the degree of connexion of the organ with the vital functions of the animal; and the genera are founded on the original disposition of inflammation to have particular modes of termination, as, for instance, in boil and whitlow to suppurate, in carbuncle to slough, and in mumps to resolve; and this disposition, he justly observes, is so strong as to render it extremely difficult to procure any other termination.

One of the most usual divisions of inflammations with reference to their nature has been into common and specific. Common or healthy inflammation is that which usually follows the action of mechanical or chemical causes, of which phlegmon may be taken as the general type.

Specific inflammation is distinguished by certain peculiarities in its symptoms and progress, which are to be attributed either to a special morbid diathesis or to the specific nature of the exciting cause. Thus inflammation of the urethra from a mechanical cause is common inflammation; the inflammation from gonorrhoea is a specific inflammation. The principal varieties of specific inflammation are the *scrofulous*, *syphilitic*, *rheumatic*, *gouty*, *erysipelalous*, the *gangrenous inflammation*, produced by morbid poisons, or else by constitutional causes; the *unhealthy inflammation* that characterizes cancer and all new growths of a malignant description.

Scrofulous and syphilitic inflammation affect a variety of tissues at the same time; the pe-

culiarities by which they are distinguished will be fully described in the articles *SCROFULA* and *SYPHILIS*.

Gouty, *rheumatic*, and *erysipelalous* inflammation will be described when treating of the modifications of inflammation by texture.

The peculiarities of the inflammation arising from animal poisons have been sufficiently detailed under the head *Constitutional Symptoms*; and those belonging to cancer and other new growths of a malignant nature will be considered in a separate article.

Latent inflammation.—It was observed, in the account of the constitutional symptoms of inflammation, that in some cases no inflammation exists, although many of its symptoms are present. It is a fact equally well established, that inflammation sometimes occurs, even to a considerable extent, without any indication of its existence from either local or general symptoms; or it very often happens that the more important are absent, and those which are recognized are insufficient to indicate the disease. Hoffmann was the first writer who noticed the latency of inflammation, and affirmed that he had found most intense abdominal inflammation without pain or sense of heat; and his observations were confirmed by subsequent writers. Baglivi states, "*Pleuritides frequenter sunt occultæ, quia indolentes, unde gravissimi errores in praxi succedunt.*"* Stoll has also given an interesting account of an epidemic fever, the chief character of which was a latent peripneumony; and in his *Ratio Medendi* a description is given of other forms of latent inflammations.†

Modern pathologists have confirmed the frequency of latent inflammatory diseases, the detection of which is now rendered more easy from the various improvements which have been recently made in diagnosis, more especially in the physical signs of diseases.

It is very difficult to account for the occurrence of inflammation without its characteristic signs; for not only is this latency observed in structures in which the sensibility is dull, but in those in which, under inflammation, it is most exquisite, as in pleurisy and peritonitis. It has been remarked by many practical writers that the condition of the nervous system has a material influence in obscuring local inflammations: this is more especially the case in continued fevers, in which the various local inflammations are rendered latent in proportion to the degree of affection of the nervous system. This, however, is not the sole cause, for cases of latent inflammation constantly occur where the nervous system is comparatively little if at all affected; it is important, however, in fever with moderate or severe cerebral affection, that the state of the various organs should be carefully examined, in order to discover the existence of organic inflammation.

It is also well known that some tissues, such

* Prax. Med. lib. i.

† A good account of both latent and symptomatic inflammations is given in the article *Inflammation* in the *Dictionnaire de Médecine*.

as mucous membranes, may undergo inflammation, and even changes of structure consequent thereon, without pain or other local indication of disease, although the constitution sympathizes powerfully with the inflamed organ. We have an instance of this in the equivocal nature of the symptoms of inflammation of the mucous membrane of the intestines, and in the latent symptomatic bronchitis of fever. Again, the progress of chronic inflammation is sometimes so slow and gradual that both the organ affected and the constitution become accustomed to it by insensible degrees, and even accommodate themselves to the impediment of function the lesion induces. Even the brain, which is the organ from which sensibility is derived, affords an illustration of this pathological fact, as local or partial inflammation of this organ may exist, and be proceeding to disorganization of its structure without urgent symptoms. In such cases not only are the more prominent signs, such as pain in the head, sense of weight, or vertigo, absent, but the mental powers are often scarcely affected, or only to a very slight degree, and the attention of the patient and his physician is perhaps for the first time awakened to the danger of the disease by some sudden seizure which rapidly destroys life.

Latent inflammation of the lungs has been alluded to as of frequent occurrence in continued fever, and would be frequently entirely overlooked, were the practitioner to trust entirely to the absence of the ordinary symptoms. In these cases auscultation seldom fails to detect the existence, nature, and extent of the pulmonary disease, which is often the chief source of danger. It is a well-ascertained fact also that partial or circumscribed pneumonia, catarrh, or congestion of the lungs, may exist for a considerable time without any perceptible change in the general health. If these partial chronic affections of the pulmonary organs be neglected, they often lay the foundation of more extended and dangerous disease; in such cases the value of auscultation must be admitted by the most sceptical.

Equally uncertain are the symptoms of several intestinal lesions, gastro-enteritis, and hypertrophy, and ulceration of the mucous follicles; so fallacious indeed have the symptoms of these lesions proved, that pathologists despair of fixing on their peculiar pathognomonic signs.

Chronic inflammation and even suppuration of the glandular organs of secretion, the liver and kidneys, chronic diseases of the heart, pericardium, and large vessels, originating primarily in inflammation, are among the latent affections discovered only after death.

Latent inflammation of the lungs or liver sometimes succeeds to capital operations, such as lithotomy or amputation, and to severe injuries of the head. We have already alluded to the non-inflammatory purulent deposits observed in organs after severe surgical diseases or operations.

These facts, connected with the occurrence of latent inflammation, shew the necessity of careful investigation into the history of each

case in which there is the slightest suspicion of latent disease going on in any organ essential to life. In the absence of external or evident symptoms, physiological examination may often assist the practitioner in its detection, more especially in those organs which cannot be brought under ocular or manual inspection. For example, chronic diseases of the brain may often be discovered by imperfection in the performance of its several important functions. In pulmonary inflammation, the state of the respiration as to frequency and regularity, the nature and intensity of the sounds elicited by auscultation, and the character of the expectoration, afford important guides. In intestinal inflammation, inquiry as to the presence or absence of pain, the condition of the tongue, the frequency and character of the alvine evacuations, and the other modes of exploration of the abdomen, are never to be omitted.

It must, however, be admitted, that even with the most minute and careful investigation, latent inflammations elude observation, and tend much to impress on the reflecting mind the diffidence with which we should pronounce the existence or non-existence of organic lesions during life, unless they are accompanied with such manifest signs as to render their existence and nature perfectly unequivocal.

Varieties of inflammation according to texture.—While the study of the healthy structure of the separate textures of the body has materially contributed to the improvement of physiological science, the great attention paid of late years to the diseased structure of the different animal tissues has led perhaps more than any other circumstance to a similar rapid advance in our knowledge of pathology. The merit of having first pointed out the advantages that might be obtained from investigating the modifications induced in disease by the structure of the part affected, and of making the animal tissues the basis of a new nosological arrangement, is attributed on the continent to the celebrated Pinel. We have before observed, however, that the writings of William Hunter, Cullen, and John Hunter contain many allusions to the striking differences several tissues present in their diseased structure; and that Dr. Carmichael Smith published an admirable paper in 1788, in which this learned physician took a comprehensive view of the peculiarities of inflammation as they are observed in the different sorts of organic substance found in the animal body.

We proceed to give an account of the changes of structure induced by inflammation in the principal tissues, and acknowledge the valuable information we have received on this important subject from the excellent work of Gendrin. We have consulted also, with much advantage, the works of Laennec and of Andral, and the valuable *Elements of General and Pathological Anatomy* of Dr. Craige.

1. *Cellular tissue.*—The two most obvious properties of the cellular tissue in health are its expansibility and elasticity. When examined after the full development of active inflammation and before suppuration has taken place, it

is found inextensible, hard, and easily broken down; its areolæ are filled with a red homogeneous, opaque, gelatinous-like matter, with which it is so firmly incorporated that it cannot be removed by ablation. The density and infiltration decrease from the centre of the inflammation; the redness also gradually lessens in intensity, but the vessels are enlarged, very minutely injected, and distended with blood. Where the redness disappears, the tissue has preserved its elasticity, but is filled with a yellowish serous fluid forming a greater or less degree of œdema, according to the laxity of the tissue and depending position of the part. When the inflammation has been violent, there are found in the central portion, besides the sanguineous infiltration, small cavities filled with black extravasated blood mixed sometimes with serosity or broken down fatty and cellular substance, or a puriform fluid. When these cavities are numerous, or when large and attended with extensive disorganization, there is a great risk of mortification.

If the part affected contains much of the vesicular adipose tissue, it will be variously affected according to the degree of the inflammation; when moderate, the fat is mostly resorbed; but if intense, it is broken down, mixed with the blood, and converted into a yellowish and pultaceous matter. The preceding morbid alterations constitute what is termed by Gendrin the *red infiltration*. As the inflammation proceeds towards suppuration, the redness gradually decreases, and is only very slight after the secretion of pus has commenced. The cellular tissue then becomes softer and spongy; the sanguineous infiltration is succeeded by that of a yellow puriform fluid; and this constitutes the *yellow infiltration*.

When the suppuration is completed, the pus collects into one or several cavities; the walls of these cavities are lined by a condensed layer of red and vascular cellular substance; the swelling becomes more defined and circumscribed; the surrounding œdema diminishes and a common abscess is thus formed.

The variety of inflammation just described is that belonging to common *phlegmon*, and is always circumscribed; it may take place in any part of the body, but some are much more disposed to it than others; it often occurs, for instance, under the jaw, in the axillæ, near the rectum, or urethra, &c. Phlegmonous abscesses frequently appear after febrile diseases, particularly the exanthemata, and are generally considered critical.

There is another form of acute inflammation of the cellular membrane, differing chiefly from the preceding in not being circumscribed, but spreading by continuity without any regular limits, and which has received the name of *diffused inflammation*. This is a constant attendant of the erysipelas phlegmonodes, and is occasioned also by the inflammation of veins, by sprains and external violence, by the inflammation of deep-seated fibrous textures, and that of poisoned wounds. Although frequently combined with erysipelatous inflammation, it may exist without it, and generally terminates

in diffused suppuration of several portions of the inflamed cellular tissue, and sometimes in sloughing. The first account of diffused inflammation of the cellular membrane as a separate disease was given by Dr. Duncan.

In *chronic inflammation*, the cellular tissue loses its elasticity, and becomes condensed and thickened by the uniform infiltration of a coagulated, albumino-gelatinous fluid, which fills its areolæ. It is difficult to divide with the knife, and not so easily broken down as in acute inflammation; in some cases the infiltration is of a greyish white; in others it has a red marbled appearance. The inflammation may either be circumscribed and terminate abruptly, or become diffused and surrounded with œdema. That peculiar affection of infancy called the *skin-bound disease*, originates in chronic inflammation of the cellular membrane. The whole surface of the body is swelled and hard, and the skin is cold and tight-bound. A similar disease has been sometimes observed in the upper and lower extremities of adults, especially in young women of a phlegmatic temperament, and is extremely difficult to remove.

Chronic inflammation of the cellular membrane may end in suppuration or ulceration. It never supplies perfect pus, but rather a sero-purulent viscid yellowish fluid, sometimes slightly tinged with blood; it shews no tendency to cicatrization, forming rather cold abscesses, fistulous canals, and chronic ulcers. The walls of the abscess are sometimes permanently organized, so as to be converted into a cyst.

Gangrene may be the effect of the intensity of the cellular inflammation. There is also a form which tends to destroy the vitality of the part from its commencement. This is either the effect of morbid poisons, or of an irritable and depraved habit of body; it is of frequent occurrence after poisoned wounds, and in some varieties of erysipelas, and constitutes the formidable disease termed *hospital gangrene*. The inflamed tissue becomes flabby, of a livid or black colour, intolerably fetid; and it finally separates from the living parts in the form of eschars. The moment the part has become gangrenous, all circulation, both in the blood-vessels and absorbents, ceases, and the vessels are obliterated; the truth of this, which was always taken for granted, has been fully demonstrated by a number of experiments performed by Gendrin.

Serous membranes.—It is a well-established fact that a serous membrane and the organ it invests, may each be affected with inflammation separately, although in perhaps the majority of cases the inflammatory action extends more or less from the one to the other. The serous membranes are connected with the textures which they either line or invest by a cellular tissue of different degrees of density, and it is not always easy to ascertain the exact line of separation between the serous membrane and the subjacent cellular tissue, in consequence of the great similarity of their texture. This is an important consideration in

deciding upon the thickness of serous membranes; for where the sub-serous tissue is loose and abundant, a considerable portion of it may be raised with the membrane, and add apparently to its thickness. Gendrin has given the best explanation of the causes of thickening in serous membranes. Some pathologists have denied that they are ever really thickened; but this is a mistaken assertion, as is rendered particularly evident by the changes induced by chronic inflammation.

The sub-serous cellular tissue always participates in the inflammation of serous membranes, and traces of the inflammation are observed in this tissue, before the substance and free surface of the membrane are at all affected. The first changes induced by inflammation are a red injection and serous infiltration of the connecting cellular tissue, which loses its elasticity and is easily torn; sometimes globules of air have appeared, forming a slight degree of emphysema. When the inflammation has lasted some time, this serous infiltration penetrates between the laminae of the serous membrane, causes a real increase of thickness, and renders it opaque. These changes are greater where the membrane is connected to the adjacent part by an abundance of loose cellular tissue, as is the case with the portion of arachnoid covering the brain, than where this tissue is very close and firm, as in the portion of the arachnoid lining the dura mater. The degree of facility with which inflammation is propagated from serous membranes to the adjacent parts, and *vice versa*, depends also, in a great measure, on the density of the sub-serous cellular tissue, and on its penetrating more or less into the texture of the subjacent organs.

The inflammation of serous membranes exhibits, therefore, in the beginning, patches of a uniform bright-red, confined to their adherent surface, and to the subjacent cellular tissue, which is infiltrated with serum. As the disease advances, the free surface of the membrane becomes dotted with small red points, and overrun with minute red streaks; the vessels, which before conveyed only a colourless fluid, beginning to admit red blood. The red patches gradually spread and unite together, and the number of red dots increases, resembling very small petechiae; in some cases they are much larger and stellated, constituting patches of ecchymosis. The membrane in the intervals is white and opaque, and there is a sensible increase of its general thickness, arising from the infiltration of serum between its laminae.

Some serous membranes are but very slowly injected in inflammation, and sometimes even not at all, as for instance the arachnoid; but as soon as the subjacent cellular tissue becomes red and filled with serosity, the membrane loses its transparency, assumes a milky white appearance, and is increased in thickness.

In cases of simple congestion, all the vessels of the sub-serous cellular tissue are very minutely injected, and sometimes a few of the

vessels of the membrane itself; and the great vascular injection seen through the transparent membrane has occasionally been mistaken for inflammation. The redness, however, can easily be removed by pressure and ablation; there are no permanent red dots or patches of ecchymosis; the membrane is neither thickened nor opaque; there is either no sub-serous effusion, or, if any, it is very slight, and the fluid not coagulated. It is necessary to remark that, when the redness of inflammation is only slight and of recent date, it often disappears partially after death.

One of the effects of commencing inflammation in a serous membrane is an increase of secretion, and the effusion of a serous fluid, at first limpid, and of a citron or reddish colour. This fluid contains a small proportion of albumen, which increases when the inflammation is severe, and it bears a strong resemblance to the serum of the blood. When the inflammation is only moderate or partial, the fluid may be absorbed almost as fast as it is effused, so that there is little or no accumulation. The surface of the inflamed membrane has been sometimes found unusually dry, although highly inflamed. This has occurred in cases of arachnitis, pleurisy, and pericarditis, in which the inflammation was very intense and proved rapidly fatal.

As the inflammation increases, and particularly if intense, all secretion is suspended, or it consists only of a very small quantity of bloody serum or of pure blood, as is seen occasionally in the arachnoid, pleura, and peritoneum: the effusion of blood has been sometimes very copious in pleurisy and peritonitis, and described as hemorrhagic inflammation. It is the constant effect of violent inflammation to stop both exhalation and absorption. We have stated already, when treating of congestions, that large effusions, not purulent, are more frequently the produce of congestive irritation than of active inflammation. When the inflammation abates, if, instead of ending in resolution, it is disposed to pass into the chronic state, the effusion then increases considerably, and, losing its limpidity, consists of a mixture of pus and serum: the pus is yellow or greenish, and sinks to the bottom. It is important, therefore, to remember that the period of decline of the inflammation of serous membranes is always attended with the danger of increased effusion. There is sometimes exuded, chiefly on the surface of the arachnoid, a layer of thick green pure pus, without any serous fluid or plastic coagulable lymph, and adhering but slightly to the surface of the membrane: this has been also observed, though more rarely, in the peritoneum and pericardium. Pus is effused also in the sub-serous cellular tissue; and this is the most usual form of suppuration in the arachnoid, as pus is but seldom poured out from its free surface. In the other serous membranes, on the contrary, pus is more frequently exuded by their free than by their adhering surface. The greater looseness and vascularity of the sub-serous cellular tissue in the arachnoid may

account for this difference. The serous fluid effused beneath the arachnoid, and in the pia mater, has a gelatinous appearance, and consists of coagulated albumen, combined with various proportions of serum according to the intensity of the inflammation; in some cases, one part of the effusion having been absorbed, the remainder becomes circumscribed in cavities formed by false membranes.

The surface of an inflamed serous membrane soon becomes covered, wherever the inflammation extends, with a very thin layer of an apparently albumino-gelatinous substance; when this is removed, the membrane is found to have lost its smooth polish, and appears rough. This deposit gradually becomes thicker and more adherent, and forms the rudiment of a false membrane: it is almost always accompanied with a serous or sero-purulent effusion; but in some rare cases, the effusion has been wanting. This organizable matter has been found by the experiments of Dowler and Lassaigne to consist of two parts; one concrescible and adhesive, formed of fibrine; the other fluid, and contained in the cells of the former, consisting of albumen; it constitutes what is generally known as coagulable lymph, and by undergoing certain modifications is converted into pus. When adventitious membranes do not become organized, Laennec says they are generally softened down into pus. There is a greater disposition to the formation of false membranes in the serous than in any other tissue of the body. The coagulable lymph is variously disposed; when exuded in considerable quantity, portions of it are generally separated from the surface of the membrane, and float in the shape of flocculi in the sero-purulent effusion, giving it a turbid whitish appearance, especially in the abdomen; from which circumstance arose the old opinion, that the effusion of this fluid in puerperal women was owing to the metastasis of the milk.

The lymph is sometimes deposited in the shape of small globules studding the membrane; at others it forms papillæ symmetrically arranged, or assumes a granular or a reticulated appearance; this is generally the case in the pericardium. The organizable matter itself is porous and cellular, containing a fluid that may be expressed by pressure. The soft portions of coagulable lymph that adhere to the opposite surfaces of the serous membrane, following the movements of these surfaces in the cavities of the thorax and abdomen, are drawn out into filaments, lamellæ, or cords, which, becoming organized, constitute cellular adhesions; their organization takes place in the following manner: the false membrane gradually becomes denser and more adherent, in consequence of the absorption of its thinner portion, and at last exhibits traces of commencing organization by becoming injected with blood. How to account for the presence of the blood is an interesting subject of inquiry, which has excited much discussion: it must either be brought by the vessels of the serous membrane which shoot into it, or else be spon-

taneously formed in the organizable lymph. Gendrin relates some interesting microscopic observations in support of the former opinion, for which we must refer the reader to his valuable work, not having space to quote them.* Laennec, and some other pathologists, have adduced, however, facts that seem to prove beyond all doubt that coagulable lymph possesses an independent vital property, in virtue of which it becomes organized. Laennec has shewn that portions of exuded fibrine perform the functions of secretion, absorption, and nutrition, before the slightest trace of any vessels can be discovered in them; for in some cases of peritonitis and pleurisy he found that the exhalation and absorption of serous fluids took place to a considerable extent between the layers of coagulable lymph, before they were organized; and that one layer of lymph is moreover capable of secreting another, as proved by a case he published in the *Journal de Boyer* for the year 1801. The fluids, therefore, under the influence of some vital impulse, must make channels for themselves in all directions between the fibres and laminae of the lymph; this process is justly compared by Andral to the life of some zoophytes composed of an amorphous mass of gelatine, who absorb, digest, excrete, and are nourished, although they do not present any vestige of regular organization. Serous fluids and collections of well-formed pus and of calcareous matter have been found in the centre of masses of coagulated fibrine, by Andral, Velpeau, and several others, shewing that it was susceptible also of morbid irritation. The development of various new morbid growths may, no doubt, be accounted for on the same principle.

The first traces of organization in the coagulable lymph are the appearance of a few red dots, resembling small collections of blood, and analogous to the *punctum saliens* in the vitellary membrane of the chick, the fibrine being endowed with a similar property of secreting red blood. Sometimes there are red lines or furrows running in various directions and anastomosing, so as to form meshes and net-works; and at a later period we find distinct bloodvessels, through which the blood regularly circulates. The globules of the blood probably move about in various directions, tracing passages for themselves through the lymph, until regular vessels are thus formed; or else the small trains of coagulated blood become converted into vascular tubes. Laennec states, that on examining these trains of blood, he has found them to contain small white cylindrical filaments of fibrine, permeable in the centre and containing blood, and which he considers to be the rudiments of vessels. Some of the branches of this independent circulating system finally inosculate with the vessels of the adjoining tissues. The vessels formed in a clot of blood have been successfully injected by John Hunter and Sir E. Home, as may be seen in some beautiful

* *Histoire Anatomique des Inflammations*, vol. ii. p. 551.

preparations in the museum of the London College of Surgeons. It is in the inflammation of bloodvessels that the various transformations the fibrine undergoes can be the most accurately traced.

As soon as a regular circulation of blood has been established in the mass of coagulated lymph, it begins to lose its homogeneous nature, and may assume a laminous, cellular, mucous, or fibrous texture, analogous to the structure of the tissue by which it has been supplied; the nervous and muscular tissues form the only exception. In serous membranes the filaments and lamellæ of soft lymph, after being highly injected, gradually shrink into thin transparent laminæ, until their redness and vascularity entirely disappear, and they assume the exact appearance of a portion of cellular or serous tissue; these new textures are found to be provided with bloodvessels, lymphatics, and nerves; and this affords a striking proof of the independent vitality existing in each particle of living matter. The preceding is the mode of formation of all cellular adhesions. As soon as the false membrane begins to be organized, it may become the seat of inflammation, exude on its surface soft organizable lymph, similar to that from which it has derived its origin, and undergo various transformations exactly in the same manner as any other tissue. It is evident, from what has been just stated, that the two opinions respecting the formation of false membranes may both be admitted; that there are first currents of blood traversing the coagulated lymph without vessels; that there are vessels formed independent of any communication with adjoining parts; and that some of these vessels finally anastomose with the vessels of the surrounding parts, so as to connect the circulation of the new tissue with that of the system. The period at which false membranes become vascular varies; numerous vessels have been seen on their surface twelve hours after their formation, and in other cases they have remained several months without presenting any trace of organization.

The alterations of structure produced by *chronic* inflammation in serous membranes differ from those of acute inflammation rather in degree than in kind; the transition, indeed, from the one stage of inflammation to the other is in general very gradual, and there are often intermediate and mixed cases, which it would be difficult to refer exclusively to either.

The redness is generally less, and inclines to a dark brown; the principal difference consists in the increase of thickness and density of the membrane; the sub-serous cellular tissue, which is completely filled with albuminous fluid, has become so identified with the membrane on the one side, and portions of false membrane are often so firmly connected with its free surface, that when the membrane is raised, its thickness and density appear considerably augmented. We have preserved portions of arachnoid membrane, which had been long exposed to chronic inflammation, fully as thick as common parchment. There are some-

times patches of a pearly white, perfectly opaque, and of a greater thickness and firmness than the rest of the membrane.

One of the alterations peculiar to the chronic inflammation of serous membranes is a rough granulated appearance of their surface, well described by Gendrin; these granulations are but slightly raised, white, irregularly dispersed, imbedded in the substance of the membrane, and are sometimes intermixed with a number of brown dots; the granulated bodies are firm, and never soften down or suppurate. The surface of serous membranes is sometimes also studded with masses of tubercular matter, which may acquire a considerable size; these tubercles are developed either in the substance or on the surface of the membrane, but generally in connection with adventitious membranes, and sometimes become softened. Tubercles are much more common in peritonitis than in pleurisy.

The effused fluid is mostly of a yellowish or milky white, and has a peculiar and sometimes fetid smell; it may contain portions of a flaky albuminous substance, mixed with pus, or be altogether puriform, or, as in the majority of cases, consist of a clear serum. It has been sometimes found entirely gelatinous, resembling a solution of isinglass. The quantity of effusion is usually so considerable as to distend the cavity in which it is contained, and compress the adjoining organs, as is seen in empyema and chronic peritonitis.

There are generally found false membranes, always completely organized, and in some cases very thick, and of a firm, fibrous, cartilaginous, or even osseous texture; these adventitious membranes are sometimes disposed in layers of different textures and degrees of density; they give the serous membrane an appearance of great thickening, which has not unfrequently been a source of deception; but on closer inspection the membrane will be found, beneath the adventitious tissues, not very materially altered. In some cases numerous adhesions are found, with an infiltration of pus between them; and when this occurs in the thorax, its cavity may become contracted, especially if, as occasionally happens, the pus makes its way by a fistulous opening to the surface. The cavity lined by the serous membrane may also be completely obliterated by a mass of adventitious tissue of a dense, indurated, fibrous nature, or else spongy, cellular, and filled with an albumino-gelatinous matter: this adventitious tissue is sometimes separated from the serous membrane by a thin stratum of soft lymph, especially when death has been occasioned by an attack of acute inflammation.

These firm and completely organized adventitious textures always indicate the pre-existence of acute inflammation. When an acute attack has supervened on chronic inflammation, the false membranes are found, as well as the serous membrane, of a vivid red, and covered with newly effused coagulable lymph or fresh pus, which are the products of the recent-inflammatory action; Gendrin states that it is sometimes possible to ascertain when there

has been more than one attack of acute inflammation, by the different degrees of organization of the newly-formed tissues. The fatal termination of chronic inflammation is to be attributed in the great majority of cases to the superposition of acute inflammation.

The serous membrane is sometimes found perfectly black, in consequence of the extravasation and infiltration of blood; this is the effect of an hemorrhagic congestion occurring in the course of chronic inflammation; besides the large spots of ecchymosis on the surface of the membrane, there is generally an effusion of blood into its cavity, which is mixed with the pus or serous fluid it already contained: these appearances could scarcely be mistaken for gangrene. Hemorrhage is not an unfrequent accompaniment of pleurisy, both acute and chronic: it is supposed to be occasionally the result of the rupture of some of the delicate vessels of the false membranes; the effusion is in general considerable, and causes the inflammation to become chronic. Laennec conceives that this mixture of blood and coagulable lymph favours the formation of fibrous and cartilaginous adventitious tissues, and states that he has observed in such cases a layer of dense membrane lining the costal and pulmonic pleura, and united by a third layer of a soft, gelatinous, semi-transparent substance.

Chronic inflammation has sometimes subsided leaving the effusion behind it. This is rather a rare occurrence, as the effusion generally disappears with the inflammation. There are, however, some instances of ascites and hydrothorax subsequent to peritonitis and pleurisy, and other cases, perhaps more numerous, of hydrocephalus succeeding chronic arachnitis in children. When the effusion has remained a considerable time, all traces of inflammation in the solids may have been removed. It should, however, be kept in mind that simple effusions are more generally the effect of active congestion than of acute inflammation. Chronic inflammation of serous membranes is often attended with swelling, induration, and suppuration of the neighbouring lymphatic ganglions.

There are no cases on record of the specific *gangrenous* inflammation of serous membranes. When affected with gangrene, it is always the consequence either of the violence of the inflammation of the membrane itself, or of the gangrene of adjacent tissues, such as, for instance, the bursting into the cavity of the pleura of a gangrenous abscess of the lung, and does not, therefore, require any separate description. The same may be said with respect to ulceration.

The skin.—The two organic textures of the skin, the dermis and rete vasculosum, may be separately affected with inflammation. The rete vasculosum (or corpus mucosum) is sometimes the chief seat of the inflammation, as is exemplified in erysipelas, the exanthemata or eruptive fevers, and the scaly, vesicular, and papular cutaneous eruptions. This will be described under the generic name of *erythemoid*

or *diffuse inflammation*. The rete vasculosum and external surface of the dermis may be jointly inflamed, and an eruption of pustules or tubercles, often followed by ulceration, take place, as in variola, vaccinia, and other pustular and tubercular cutaneous diseases. This will constitute the division of *pustular inflammation*. Or the substance of the dermis itself may be the chief seat of the inflammation, which often extends in this case to the subcutaneous cellular tissue, of which furunculus, anthrax, &c. are examples. This will form a third division into *inflammation of the dermis*. We have followed in this respect the classification of Gendrin.

The inflammation, however, in each of these divisions is by no means always limited to the one texture, but, if very acute or of long duration, extends to the others, as might naturally be expected, considering the intimate connexion existing between the different parts of the skin. Cutaneous affections often undergo in this manner great modifications in their appearances, one form of disease assuming in succession the characters of several others, or there being mixed cases; this will account for the great difficulty often experienced in assigning with accuracy every case to its proper class in the nosological arrangements of cutaneous affections.

Acute erythemoid inflammation comprehends the inflammation arising from blisters, burns, erysipelas, scarlatina, rubeola, &c.; it is almost always more or less diffused, and characterized in its commencement by a bright uniform fiery redness of the surface of the skin, called *rube-faction*; the exhalation being suspended, there is a dry burning heat, and also a very slight degree of tumefaction, perceptible only to the touch. If the inflammation increase, the epidermis becomes detached and raised, either in large bullæ and phlyctenæ, or small vesicles, by the effusion of a limpid yellowish serosity. When the epidermis is removed, the inflamed surface appears of a rosy tint slightly yellow; it is covered with red streaks, is rather tense, and exquisitely painful; small drops of limpid serum are constantly exuding. If the inflammation subsides at this period, the redness, pain, and serous secretion diminish, and the surface becomes covered with a pellicle of soft plastic lymph, which is gradually converted into a new cuticle. When the inflammation has been violent and the epidermis detached, a thick layer of a white concrete viscid lymph is sometimes found under it, as is seen in burns and blisters.

When the inflammation ends in resolution without phlyctenæ or vesicles, the epidermis often falls off in small furfuraceous scales, under which a layer of new epidermis of a shining bright or violet red has been formed, and which does not assume its natural colour until after some time, as is exemplified in rubeola and scarlatina.

If the inflammation, however, is intense and prolonged, there is poured out a reddish serum, which gradually becomes turbid, sero-purulent, and at last completely purulent. When sup-

puration is fully established, the inflamed surface is of a bright red, has a rugous or villous appearance, and portions of lymph are sometimes exuded along with the pus. As the inflammation and suppuration diminish, the small granulations, which resemble those of common wounds, gradually become lined with a thin pellicle constituting the new epidermis.

Intense inflammation of the rete vasculosum extends frequently to the dermis and subjacent cellular tissue, as is seen in the erysipelas phlegmonodes and in severe burns; the skin is then tumefied and tense, and its redness does not disappear on pressure. The dermis and subjacent cellular tissue are injected with a red gelatinous fluid, and there are sometimes spots of ecchymosis or of extravasated blood on the surface. The inter-areolar adipose substance is absorbed; the texture of the dermis has lost its elasticity, is easily lacerated, and appears as if carnified. There is sometimes extensive suppuration and sloughing of the cellular tissue. These are the various appearances presented by the skin in erythemoid inflammation, from the slightest to the most intense erysipelas.

If the skin has been slightly inflamed just before death, every trace of inflammation disappears in a few hours after death. At a later period, however, Gendrin states that the portion of skin which was inflamed is found in a state of passive congestion, and the epidermis becomes sooner detached by putrefaction than in other places. But when the cutaneous inflammation has been at all severe, the rete vasculosum always continues much injected after death, and there is sometimes also a certain degree of sub-cutaneous œdema. A few days after death the injection and œdema are considerably increased by cadaveric congestion, which might lead to the belief that the inflammation had been much greater than it really was; this arises from acute inflammation increasing the tendency of the solids to putrefy by lessening their force of cohesion.

The inflammation which gives origin to pustules (*pustular inflammation*) is of a phlegmonous character, each pustule bearing a considerable resemblance to a small phlegmon. They make their appearance first by small red dots, which increase gradually to round spots of a bright red, a little raised in the centre, giving a feeling of roughness or rugosity to the skin; the swelling of these spots goes on increasing until they form small, round, firm, red tumours, imbedded more or less deeply in the dermis, each tumour being surrounded by a red areola. The progress in the development of these pustules is very variable, being in some diseases fixed and regular. They differ also in their form, structure, and mode of termination. Some, as variola, are flattened, have several cells, and are depressed in the centre, the depressed part being attached to the dermis by one or several small white fibrous connections.

An eruption of acute pustules is also occasioned by the application of a variety of irri-

tating substances, and particularly of tartar-emetic ointment and mercurial plasters; they are small, depressed in the centre, and have only one cell containing a little pus. Pustules may be either disposed in groups or irregularly scattered over the body; some varieties are acuminate instead of being depressed at their apex. Pustular diseases of a chronic character will be considered under the head of *chronic pustular inflammation*.

Inflammation of the dermis, *corion*, or *cutis vera*, includes chiefly two varieties of disease—*furunculus* and *anthrax*: the dermis is undoubtedly the principal seat of the inflammation in these affections, although it extends in general more or less to the subjacent cellular tissue.

Furuncle commences with a pimple in the skin, which gradually increases until it forms a small tumour of a conical shape, with a pustule on its apex, and generally very hard; it is of a bright or dark red, accompanied with burning heat, and excessively painful. The vascular and cellular processes that fill the areolæ of the dermis appear to be the primary seats of this inflammation, which afterwards spreads to the surrounding parts; it terminates in suppuration, and in the expulsion of a small body called *core*, after which the little abscess heals in the usual manner.

Cores have generally been considered as portions of cellular tissue which have mortified, in consequence either of the violence or unhealthy character of the inflammation; and this appears the more probable that a fetid and unhealthy pus is discharged from the abscess with them. Gendrin, however, is of opinion that cores are not sloughs, but a morbid secretion or pseudo-membrane, the product of the inflammation of the inter-areolar cellular processes. As they become enlarged, they distend the fibrous sides of the areolæ, creating great tension and a certain degree of strangulation; they act as foreign bodies, in exciting considerable inflammation in the sides of the areolæ; these are at first in a state of red infiltration, and adhere firmly to the cores; but as suppuration advances, the latter are gradually loosened and finally expelled. Gendrin states that cores consist of a viscid semi-transparent homogeneous yellowish white substance, and that he has never been able to discover in them any vessels or the least appearance of organization. The opinion of so accurate a pathologist is entitled to considerable weight, and should not be rejected without further careful investigation of the subject.

There is considerable analogy between the anatomical characters of *anthrax* and *furuncle*; the former is, however, a much more extensive and severe disease; it occurs generally at a more advanced age, is connected with a vitiated state of the constitution, and sometimes with the existence of a morbid poison in the system, as, for example, in pestilential fevers. Gendrin considers anthrax to differ only from furunculus in the circumstance of a number of the areolæ of the skin being affected with inflammation instead of one, and he states that he has seen the portion of af-

fect skin pierced in this manner with a great many holes. There is evidently, however, mortification of several portions of skin and cellular tissue, besides a new inflammatory deposit.

Anthrax commences, like furuncles, with a small pimple, which extends rapidly both in breadth and depth until it forms a large flat tumour, only a little raised above the surface of the skin, and extending under it into the cellular tissue; it is nearly immovable, very hard and painful, of an intensely burning heat, and of a deep but rather dark red; it feels like brawn, is distinctly circumscribed, and its surface is covered with livid pustules or vesicles; as the disease advances, the skin mortifies in the centre and ulcerates at the circumference; a fetid unhealthy pus is discharged, and after a considerable time and much suffering a large slough is separated, consisting apparently of the union of several sores, and completely sodden with pus. When the slough is removed, there remains a large ulcer, which heals by a slow suppurative process.

There are three varieties of anthrax: one benign and mild; another malignant, having a greater disposition to mortification, of which the anthrax of the plague is a good instance; and one variety of a chronic character, similar to chronic furunculus. The lymphatic glands in scrofulous subjects sometimes undergo a sloughing inflammation called glandular anthrax.

We have examples of *chronic erythemoid inflammation* in chronic erysipelas, old blisters, and many of the scaly, papular, and vesicular cutaneous diseases, such as lepra, psoriasis, ichthyosis, lichen, prurigo, pemphigus, rupia, herpes, scabies, miliaria, and eczema. In those cases in which the epidermis is not raised into vesicles or bullæ, the surface of the skin is injected, of a dark red colour, not removed by pressure, dry, hard, rather thickened, and covered with a number of small red elevations like enlarged papillæ, which give it a rugous appearance; the epidermis falls off in scales which are frequently renewed, or it forms scabs, from under which there sometimes oozes a viscid puriform fluid having a disagreeable smell. When these scales drop or are removed, they are generally succeeded by others.

The epidermis is raised in other cases into vesicles, phlyctenæ, or bullæ, containing a yellowish serum. The fluid of the vesicles may be resorbed, so that the detached epidermis forms a thin scale which falls off, as soon as a new epidermis has been formed; or the fluid concretes into a scab, which is also removed after the formation of a new epidermis. There is frequently a succession of new vesicles and scabs on the same part. The denuded skin under the phlyctenæ and vesicles is injected, red, and sometimes supplies a series of scabs without healing. When blisters have been long kept open, or when the chronic inflammation has been severe, as in psoriasis inveterata, the texture of the dermis is much altered; it is thickened and injected with a gelatinous fluid of a yellow red, has lost its elasticity and density, being easily torn, and

entirely deprived of adipose substance; the subjacent cellular tissue is also more or less thickened and œdematous. When the surface has been long denuded and suppurating, it is covered with soft, flabby, bleeding granulations of a yellowish red colour, and sometimes with layers of whitish concrete lymph, which is removed with the dressings. In ichthyosis the epidermis is enormously thickened, and acquires the hardness of horn; and in the common elephantiasis the dermis and subjacent cellular tissue are sometimes converted by the infiltration of an albumino-gelatinous matter into a new texture, thick, dense, homogeneous, and very like brawn.

Chronic pustular inflammation includes the various forms of impetigo, porrigo, ecthyma, acne, and mentagra, to which we may add the different kinds of tubercles into which the pustules frequently degenerate.

The pustules of these chronic cutaneous affections differ in their form, size, and situation; they are either large, acuminate, and with a hard and inflamed base, resembling in some cases small furunculi, as in ecthyma, impetigo, and acne; or they are small, round, granulated, and covered with thick scabs, as in porrigo; they may be dispersed over every region of the body, as in ecthyma and the impetigo sparsa, or be confined more particularly to certain parts, as in impetigo figurata, acne, and porrigo. Their first appearance is usually indicated by minute, red, itching, spots, which are soon raised into small round tumours; they are at first hard, either red, or of the colour of the skin, imbedded in the rete vasculosum and generally also in the dermis; the rete vasculosum around them is deeply injected, and of a yellow red, and the injection extends in severe cases to the entire thickness of the dermis, and even to the subjacent cellular tissue.

The pustules quickly suppurate and then contain an opaque and viscid fluid, or thick pus of a peculiar and disagreeable smell, similar in porrigo to that arising from mice. The suppuration is followed by desiccation and the formation of scabs; these are either thick, prominent, conical, and of a green or brown colour, as in impetigo figurata; or yellow, concave, and cupped, as in the porrigo favosa; or disposed in flat, irregular, lamellated masses, as in porrigo larvalis and lupinosa. When the part is thickly studded with small pustules, as in porrigo, the whole of the intervening skin is inflamed, tumefied, red, and exoriated, secreting a thick purulent matter, which, uniting with the crusts of the pustules, forms large masses of thick scabs; there are often intermediate fissures in the scabs, through which matter is constantly discharged. The inflammation is attended also sometimes with abscesses of the scalp. The sebaceous follicles are considered by some to be the principal seat of the inflammation in acne and mentagra, and the bulbs of the hair, in porrigo. Syphilitic pustules are characterized chiefly by their copper violet colour and great disposition to ulcerate; they are also sometimes depressed in the centre or flat, especially in children. A de-

tailed account of pustular affections of the skin will be found in the separate articles on cutaneous diseases.

Tubercles are larger and less inflamed on their first appearance than pustules. Some never suppurate, remain indurated and have but little vascularity, such as the verrucæ and moluscæ. Others, after acquiring a certain size, become inflamed, suppurate, are covered with thick scabs, and finally degenerate into unhealthy ulcers, which is the course of syphilitic tubercles. There are also a variety of fleshy excrescences and vegetations of the skin which may be considered as modifications of tubercular inflammation; they occur frequently after syphilis, and sometimes in scrofulous subjects; but occasionally also as a mere local affection.

Phagedenic inflammation of the skin is of a peculiarly malignant character; it leads to the formation of unhealthy ulcers, which spread more or less rapidly, destroying, by a process of suppurating and sloughing, the parts which they invade. It may affect almost every tissue of the body, but the skin is more subject to it than any other; it may supervene on other forms of inflammation, and sores of every description may assume a phagedenic character; this is more particularly the case with syphilitic and scrofulous ulcers, in which acute phagedenic inflammation is not unfrequently excited by the irritation of mercury. Phagedenic inflammation is sometimes idiopathic, especially in constitutions which have inherited either a scrofulous or syphilitic taint, or both.

There are two varieties of phagedenic ulcers, the *acute* and the *chronic*. In the *acute* the edges are swelled, inverted, jagged, and intensely red. The surface of the ulcer is of a fiery red, and discharges blood, accompanied with burning heat and extreme pain; it secretes a thin, sanious, acrid fluid. The acute phagedenic ulcer often spreads very rapidly, destroying the parts in some measure by a sloughing process. This form of phagedenic inflammation frequently occurs in scrofulous and syphilitic ulcers.

The *chronic* phagedenic inflammation of the skin commences generally by the development of small pustules, which soon degenerate into tubercles, the summities of which ulcerate; the edges of the ulcers are raised, indurated, of a violet red colour, less painful, and more circumscribed than in acute phagedena; the texture of the skin and subjacent cellular tissue is converted into a hard homogeneous substance resembling brawn; the bottom of the ulcer is of a dirty white, and covered with flabby granulations; the discharge is seropurulent, fetid, and sometimes sanious. The secretion frequently concretes, forming thick hard scabs, under which the ulcer continues to extend; this form of phagedena spreads more slowly, but destroys with the same certainty as the acute; it enlarges chiefly at the circumference, while syphilitic ulcers have a greater tendency to extend in depth; it sometimes heals in the centre while spreading at the edges,

and large soft vegetations arise occasionally from its surface; it varies in activity, being at one time indolent and at another more inflamed; the surrounding skin is often of a violet red, studded with hard tubercles or pustules of impetigo, and greatly predisposed to be affected with erysipelatous inflammation. After healing, these ulcers leave thick, red, and deeply furrowed cicatrices similar to those of burns.

The preceding form of phagedenic inflammation is principally observed in the formidable disease called lupus, and in the elephantiasis Græcorum.* There is a variety of phagedenic ulcer of the skin more superficial than the preceding, appearing in the form of tortuous lines or furrows, and called sometimes herpes serpens or exudens.

The skin is extremely liable to be affected with *cancerous* inflammation, cancer frequently having its origin in the skin, and spreading afterwards to the subjacent tissues; it commences by small pimples or pustules, which, after remaining for a greater or less interval of time hard and indolent, assume the form of tubercles, become more inflamed, are affected with lancinating pains, and finally ulcerate; the ulcers are deep, have hard, jagged, indurated, inverted edges, with a pale red, sanious, soft, and fungous surface; they gradually extend in depth and circumference; the surrounding tissues are converted into a new homogenous substance, intersected with white fibrous or fibro-cartilaginous bands, and presenting often small cells containing a sanguineous or cerebriform softened matter. Cancer of the skin occurs most frequently on the nose, lips, cheeks, prepuce, scrotum, and at the margin of the anus. We must refer the reader for a more detailed account of the various forms of cancer to the article SCIRRHUS.

The skin is more subject to idiopathic *gangrenous* inflammation than any other part, because it is most exposed to the direct action of deleterious agents, and it is also the principal seat of critical and symptomatic inflammations.

One of the frequent causes of gangrenous inflammation of the skin is poisoned wounds. The first effect that follows the introduction of any venomous matter into the skin, is the appearance of a small vesicle, attended with much itching; the skin under the vesicle is hard, and of a livid red around it; the hard tubercle in the centre, which is mostly insensible, soon assumes a black colour; the red areola spreads, the skin becomes tumefied, more livid, and covered with small phlyctenæ; the black gangrenous eschar extends rapidly from the centre to the circumference; the swelling of the skin and cellular tissue increases with considerable œdema and sometimes emphysema; the gangrene extends also in depth to the subjacent cellular tissue, and reaches frequently the

* An interesting account of two cases of the true elephantiasis that occurred in this country is given in the Medico-Chirurgical Transactions for 1815, by Mr. Lawrence and Dr. Southey.

tendons and bones, causing extensive sloughing. The constitution soon begins to suffer, and gangrenous erysipelas appears in several other parts of the body. We have already seen, however, when describing the constitutional symptoms, that the patient sometimes sinks from the destructive influence of the poison on the system, without any local affection.

In some very unhealthy constitutions, erysipelas occasionally assumes a gangrenous character from its first appearance; the inflammation is deficient in activity, and attended with considerable œdema; the skin is of a livid or dark red, covered with a number of phlyctenæ, beneath which are observed black livid spots; the portions of skin thus affected soon mortify, and the gangrene spreads with rapidity, creating large sloughs both of the skin and cellular tissue. In some cases small ulcers appear on the surface, or collections of matter are formed in the cellular tissue, destructive supuration being thus added to the gangrene.

The skin may also be affected with gangrene in consequence of the intensity of the inflammation, or from the direct action of irritants, such as intense heat, chemical agents, &c.: or finally from the benumbing effects of excessive cold.

(A. C.)

Inflammation of mucous membranes.—Previous to entering upon the description of the inflammatory affection of mucous membranes, we think it necessary to describe the healthy structure of these tissues.

In the greatest part of its extent, mucous membrane consists of a spongy tissue, more or less soft, and varying very much in thickness: this is the mucous corion, on the surface of which the ultimate vascular ramifications are found. An epidermis or epithelium is very distinctly seen on this corion in some situations, that is, at the orifices of mucous cavities. It diminishes in thickness as we trace it from the origin of the mucous membranes, till in the more internal parts it eludes our observation; in fact the existence of the epithelium in the internal mucous membranes cannot be demonstrated.

Mucous membrane is especially remarkable for a series of mucous crypts or follicles, which are uniformly to be met with, varying, however, in number and arrangement in the different situations. An examination of the foramen cœcum at the base of the tongue and of the tonsillitic follicles will clearly expose their structure. In the gastro-intestinal mucous membranes they are found in great numbers, and under two different modes of arrangement: in the one case they are isolated and distinct from each other, (*glandulæ solitariae*), under which form they are chiefly met with in the large intestine; in the other they are deposited in clusters, (*glandulæ aggregatæ*), and are to be seen chiefly in the small intestine, in the duodenum, and the colic extremity of the ileum.

Two varieties of eminences are found upon the free surfaces of mucous membranes; of these the most voluminous are called *papillæ*, of which

the best-marked examples are on the tongue, glans penis, and clitoris. In parts provided with papillæ, the mucous membrane is furnished with a distinct epithelium.

The second class of eminences are the *villi* or *villosities*, which are found most prominently on the gastro-intestinal membrane. They are highly vascular, and the recent observations of Leuret, Lassaigne, and others, leave no doubt that in them the capillary extremities of the lacteals commence. They appear, therefore, from this fact, as well as from other considerations, to be materially connected with the absorbing function. The pathologist should bear in mind that these minute bodies may be injected with equal facility either from the arteries or mesenteric veins, which latter, being destitute of valves, permit the injected fluid to pass in a retrograde direction.

The healthy colour of those portions of the mucous system which are near to the orifices, is so obvious to the most superficial observer as to render any remarks upon it unnecessary. The natural colour of the more deep-seated portion varies in infancy, adolescence, and old age. At the former, it is transparent or of a rosy white colour; at the latter age, it is of a dull white, but retains a slight rosy hue; in old age, it becomes ash-coloured. The process of digestion increases the rosy colour of the membrane, and sometimes, especially with young subjects, induces a cherry red-colour, obviously by increasing the flow of blood to it. Gendrin has found that fasting for any length of time also has the effect of heightening the colour of the membrane, which may be removed by nourishing the animal.

That the kind of death, moreover, has considerable influence upon the colour of the membrane is obvious, as in cases of death from chronic disease, from anæmia, and from asphyxia. Lastly, Gendrin found the mucous membrane increased in colour during the traumatic fever succeeding to a severe wound inflicted on an animal.

1. *Acute erythemoid or diffuse inflammation.* A change of colour is the most prominent mark of inflamed mucous membrane, occasioned by an increased vascular injection of those portions of the membrane to which irritation has been applied. This change of colour varies in extent and intensity, the membrane exhibiting either slight and superficial arborescent networks of an arterial red colour, or uniform spots, either red, brown, or black, and occupying the whole substance of the membrane.

The many varieties of vascular injection which mucous membrane in general, but that of the alimentary canal especially, presents, render it a matter of moment to determine, with as much precision as possible, those signs which characterize the vascularity of inflammation. Pressure diminishes the natural redness, or that of congestion, but does not produce that effect on the colour of an inflamed part. If the inflammation have existed for even a short time, maceration does not cause the redness totally to disappear, and those who are in the habit of making morbid preparations know how well

the inflamed membrane exhibits its vascularity when dried and varnished, as if the inflammation had excited a greater degree of cohesion between the blood and the coats of its containing vessels.

In the highest degree of inflammatory action, we not unfrequently find spots of extravasation, the submucous tissue being injected with blood, which either has escaped from the rupture of a minute capillary, or transuded through the parietes of the vessels. In those membranes which present numerous villi on their surfaces, inflammation begins by red points or dots, which appear to occupy the extremities of the villi, giving them a tumid erectile appearance. This condition of the membrane may be clearly demonstrated by examining it under water, or with the aid of a lens, or even by viewing its surface in an oblique direction. As the inflammation advances, the number of points increase, appear to coalesce, and give an aspect of diffused redness to the surface of the membrane. When the colour of the mucous tissue is naturally red, the increased color is uniform, nor is there an obvious appearance of arborescent or capilliform injection.

The surface of inflamed mucous membrane loses much of its natural softness; it is rugous, and if it be covered with papillæ, these bodies are rendered more prominent and swollen than natural; if with villi, a similar effect is produced; if crypts abound on the surface, the orifices of these secretory organs are less apparent, from the swollen condition of their margins.

Increase of the thickness of the membrane is a constant attendant on inflammation, as is well seen in coryza and laryngeal inflammation; it is in general immediately consequent on the redness, and in proportion to the degree of vascularity. At an early period of the attack, the density of the membrane appears to be also increased, but as the inflammation advances, the membrane becomes softened. The condition of the submucous tissue is deserving of attention; it is frequently infiltrated with a serous, or occasionally a bloody fluid, by which the thickness of the membrane is increased: this is more conspicuous when there are folds, such as the *valvulæ conniventes*.

A particular affection to which some mucous membranes are more especially liable may be here alluded to; it is, as Gendrin has well observed, intermediate between inflammation and oedema, and is distinguished by the term *œdematous*, on account of its principal characteristic being extreme infiltration of the substance of the mucous membrane, as well as of its submucous tissue, with serum. Of this, œdema of the glottis, and the œdematous condition so often seen in the velum and uvula, present familiar examples. The adhesion of the mucous membrane to the surfaces which they line is diminished considerably by inflammation, so that they are detached from them with facility—a facility, however, which varies according to the natural thickness of the membrane, and the structure of the connecting cellular tissue.

At the first invasion of the inflammation, the secretion of the membrane is somewhat increased in quantity and less viscid than natural; when the inflammation is at its height, the secretion is almost suppressed, and the membrane consequently dry; but as this period is always of short duration, the secretion is soon re-established, and often discharged in considerable quantity, assuming at times a greenish colour, and being occasionally tinged with blood. The orifices of the follicles are generally enlarged and open. Towards its decline, the secretion sometimes assumes a puriform character, and is in general very copious; this has been long known in the schools as exemplifying purulent secretion without solution of continuity.

Acute inflammation of mucous membrane sometimes terminates rapidly in gangrene, giving rise to the formation of large sloughs, which, when thrown off, leave a considerable solution of continuity. Such is the case in certain inflammations of the throat, (*cynanche maligna*), and in some severe forms of dysentery; in which disease the mucous coat of the large intestine often presents several patches of this kind.

The action of some acrid poisons excites in mucous membrane a high degree of inflammatory action, of which, universal tumefaction of the membrane, and sometimes black or livid spots, produced by the infiltration of the subjacent tissue with dark blood, are the unequivocal signs.

Such are the appearances which characterize erythemoid inflammation of mucous membranes: all are of great value, in deciding the question as to the existence of inflammatory action, a point in the determination of which great caution should ever be observed.

The anatomical characters of chronic inflammation of mucous membranes differ in some essential particulars from the acute, the appearances varying according to the stage and duration of the inflammation. It occurs in patches or stripes, the intervening portion of the membrane preserving its natural pale colour. In the more recent cases, the colour is of a dusky red, inclining to a mahogany tint: the substance of the membrane is thickened and increased in density, the mucous follicles are slightly enlarged, and the secretions are copious, viscid, ropy, or puriform, as in chronic ophthalmia, bronchitis, gonorrhœa, or catarrh of the bladder. When the inflammation has been of longer duration, the dusky redness of the former stage passes into an ash-grey colour, interspersed with black spots or streaks, which gives the membrane a dark mottled appearance. The thickening also not only disappears, but the membrane becomes even thinner than natural, and sometimes considerably softened; this softness, when combined with serous infiltration of the submucous cellular tissue, is the cause of the mucous being so easily detached from the muscular coat, and gives the internal surface of the membrane an œdematous appearance. In cases of inflammation of the mucous membrane of long standing, this tissue is sometimes still more altered in structure; it becomes hyper-

trophied and indurated; its colour changes to a grey white; its surface appears rugous and granular; and, finally, effusion of an albuminous matter, between all the coats of the intestine at the points of disease, obliterates the structure so entirely, as scarcely to leave any traces of its original configuration. Vegetations resembling warts are also in those latter instances not unfrequently found on the mucous surface. These appearances, which affect exclusively villous membranes, may be often observed in cases of chronic dysentery.

2. *Pseudo-membranous inflammation.* Mucous as well as villous membranes, when acutely inflamed, effuse a concrete fluid, which, neither in appearance nor in chemical properties, can be distinguished from that which is formed by serous membranes.

It has been affirmed by Bichat and others that mucous membranes do not effuse lymph or contract adhesions. On this subject Dr. Craigie observes that the question of adhesion depends not so much upon the fact of albuminous exudation as upon the anatomical disposition of the cavity or canal, whether it be sufficiently small to favour the approximation of opposite and corresponding surfaces. Thus in the gastro-intestinal mucous membrane, which is in general capacious and distended either incessantly or frequently with foreign bodies, mutual approximation is too imperfect to admit of adhesion. Yet by some observers this is asserted to have happened. In situations, on the contrary, in which mucous surfaces line narrow tubes, as the lachrymal duct, the Eustachian tube, the urethra, and perhaps the fallopian tubes, obliteration of the canal by adhesion of its sides is more frequent.

It is certain that the surgeon has not unfrequently occasion to observe corresponding points of narrow canal, as the urethra, adhering apparently by concretion of its sides. Dr. Craigie concludes from these facts that the assertion of Bichat, of the inaptitude of mucous surfaces to adhere, requires some limitation; and from other facts, he is disposed to infer that one of the conditions necessary to the albuminous exudation and the subsequent concretion of mutual surfaces, consists in the destruction of the mucous epidermis by abrasion or ulceration.

These false membranes adhere in some instances to the mucous surface by which they are effused, and often form an exact mould of the cavity or canal in which they occur: they are of a much softer texture than the false membranes which exude on inflamed serous surfaces, and have no trace of organization. When this membraniform exudation succeeds to acute inflammation of the mucous membrane of the mouth and pharynx, it constitutes that disease which Bretonneau describes under the name *Diphtheritis*, which first appears in the form of small points or streaks of redness of the mucous membrane, but without much swelling; this is succeeded by the exudation of isolated white spots, chiefly on the follicles at first, which gradually increase in number, and cohere in patches, occupying a more

or less considerable portion of the surface of the uvula, tonsils, and posterior pharynx. These membranous formations, when detached, vary in thickness, but are generally white and transparent; when they are of an ash-grey colour, this arises from their being tinged with blood. This colour, and their being often accompanied with fetor, render them liable to be mistaken for gangrenous sloughing of the mucous membrane of the throat. They may be confined to the mouth and pharynx, or they may extend and dip into the larynx, cesophagus, nasal fossæ, or Eustachian tube, and when they are thrown off, are in some cases renewed several times. Andral met with a case of inflammation of the pharynx with membranous exudation on the palate and tonsils. The inflammation spread to the larynx, and destroyed the individual. On opening the body, false membranes were found not only in the larynx, trachea, and bronchial tubes, but on the inner surface of the nostrils and around the ethmoid cells. The inflammation in this case had thus spread from the pharynx to the vocal and respiratory organs, and into the cavity of the nose.*

The air-passages are more frequently covered with false membranes than any other mucous surface; and it may be observed that children are more subject to affections of the mucous membrane of the air-passages—the formation of false membranes is consequently more common at this than at other periods of life. When they form in the air-passages, they vary in thickness and consistence; some are transparent, and of extreme delicacy; others are several lines in thickness, and so consistent, that they can not only be removed entire, but afterwards preserve their moulded form. A viscid fluid is interposed between the inflamed surface and the false membrane, by which their adhesion is prevented: in some instances minute filaments have been observed in these exudations, by which it has become united to the surface on which it has formed.

We have already mentioned that the membrane which is formed in diphtheritis sometimes dips into the upper part of the larynx. Inflammation of the mucous membrane of the larynx is, however, seldom followed by membranous exudation, but generally, when intense, the inflamed membrane is covered with thick viscid or semi-puriform fluid, which is most abundant in the sacculi of the larynx. Minute portions of fibrine may be occasionally effused, and give a greater degree of consistence to the exudation. The pathology of these cases is, however, very different from that of laryngitis, in which the inflammation is seated in the submucous cellular tissue by which the mucous membrane is united to the cartilages of the larynx.

In tracheitis, or croup, the inflammation is followed by the rapid exudation of a tenacious membranous substance, which is moulded to the form of the trachea. This false membrane is generally limited to the trachea and of a tough consistence: when it extends to

* Arch. Med. 1825.

the bronchia it is much softer, and in the smaller bronchial tubes it becomes quite fluid. The impediment to the respiration in croup is to be attributed in a great measure to the presence of these false membranes, but also to the swelling of the tracheal membrane, and to the bronchitis which very often accompanies the disease. The spasmodic affection of the muscles of the larynx, which occasionally accompanies croup, adds much to the sufferings and danger of the patient: when the disease proves fatal, the death is owing to the mechanical obstruction of the air in the trachea and bronchial tubes by the false membranes.

The formation of false membranes is also a consequence of inflammation of the gastro-intestinal mucous membrane; and, as noticed by Andral, it occurs more frequently in its supra-diaphragmatic than in its infra-diaphragmatic portion. In children, the mouth, pharynx, and œsophagus are occasionally lined with a membraniform exudation, which terminates abruptly before it reaches the stomach. After puberty, these formations are equally uncommon, either on the internal surface of the stomach or intestines, Andral having never seen any either in the stomach or small intestines, and in only two instances had he observed false membrane lining the large intestine. Cases, however, of this kind have been observed in adults. We lately attended a female who frequently voided a considerable quantity of false membranes from the bowels. They appeared, from their size and form, to have been effused on the mucous surface of the small intestines, and evidently, from the history of symptoms, were the result of chronic gastro-enteritis. The disease disappeared after repeated local detractions of blood from the surface of the abdomen, counter-irritation, and a bland diet.

Andral mentions a remarkable case of a young girl of twelve years of age, in whom all the air-passages were lined with false membranes; they were found also in the pharynx, œsophagus, and stomach, where they existed in the form of large bands, extending from the cardiac to the pyloric orifice, beyond which point they did not reach. The mucous membrane was much more red beneath than in their intervals.

Pathological writers allude to the discharge of portions of the mucous coat of the bladder. There can be little question, we presume, that these morbid products are false membranes which have formed on the internal membrane of the bladder, and after being detached, have been expelled with the urine. The urethral mucous membrane appears to assume the puriform secretion rather than exudation of lymph. The inflammation frequently extends to the sub-mucous cellular tissue, and by infiltration and thickening of this structure, contraction or stricture is induced.

False membranes occasionally form in the cavity of the uterus, in consequence of an irritated or inflamed state of the uterine mucous membrane. These membranes are sometimes thrown off in detached shreds after painful

menstruation, or at irregular periods, when the internal surface of the uterus is inflamed. In some instances, they bear the exact mould of the cavity of the uterus, and have such a degree of consistence as to admit of manual examination and even preservation in alcohol. Sterility is a common effect of these false membranes of the uterus.

3. *Pustular inflammation* has its seat chiefly, if not entirely, in the mucous crypts or follicles. We not unfrequently meet with a simple enlargement of these glandular organs (glandular so far as they are connected with a secreting function), in certain forms of fever, as well as in other anomalous affections. When acute inflammation attacks one of these follicles, it becomes enlarged, swollen, and vascular. The mucous membrane and subjacent tissue soon exhibit marks of the inflammatory action; and when the membrane is villous, the villi are red and increased in size. A pustule is formed, round and prominent, more or less acuminate; and if a set of aggregated follicles become inflamed, the pustule is more flattened, and has a larger circumference. Frequently we find on the apex of these bodies a minute orifice, indicated by a dark spot, through which by pressure we soon squeeze out a mucous or puriform fluid, whilst in others we cannot observe any trace of an orifice.

The pustules of mucous membranes which we have most frequently an opportunity of examining, are those more especially seen in the membrane of the mouth and pharynx. They are usually known under the name of aphthæ, and are essentially the same in their mode of origin, as those which are developed on the deeper-seated membranes.

The pustules on the inner surface of the intestinal tube often appear in a form nearly resembling that of the variolous pustule. The occurrence of these intestinal pustules in connexion with fever has been minutely noticed by Ræderer and Wagler in their history of the Gottingen epidemic, and afterwards by Petit, Pinel, and others. They have been supposed to coexist frequently with the cutaneous eruption of small-pox, and we may add, that although this is not a very frequent occurrence, yet a sufficient number of cases are on record to establish the fact.

We may, however, state that the possibility of the existence of pustules on a membrane devoid of an epithelium has been called in question. But if it be considered how numerous are the mucous crypts, and that in general, if not always, the pustule (so called) is found to occupy one or more of these, we can have no difficulty in accounting for its formation. In some instances, the apex of the pustule presenting a minute opening, in others that opening being closed by adventitious membrane, the follicular pustules of mucous membranes may be said to correspond in every respect with the pustules of the follicles and sebaceous glands of the skin, as exemplified in acne, mentagra, porrigio, and some varieties of impetigo. The analogy between the pustules that occur on membranes provided with epithe-

lion and those of the skin is sufficiently obvious.

It may be mentioned that the most constant and frequent locality of pustular inflammation in the intestinal canal is about the cæcal half of the ileum. This is the form of disease described by Bretonneau under the appellation *Dothincnteria*. (See FEVER.)

4. *Ulcerative inflammation*. After a pustule is fully formed, its centre soon becomes depressed, and it loses its conical form. In some cases, this depression is owing to an enlargement of the orifice of the follicle, but more frequently it is produced by an incipient ulcer. The increase of this depression, and the gradual disappearance of the pustule, indicate the progress of the ulcerative process; finally, a circular ulcer, or when several follicular ulcers cohere, a patch of ulceration occupies the site of the original pustule. This is the most frequent commencement of ulcers of mucous membranes: their numerous variations of form, extent, and depth, are dependent on the intensity of the inflammation, and the extent to which the neighbouring tissues are involved. Ulceration of a mucous surface does not always originate in the follicles: it is sometimes the result of acute inflammation of both mucous and villous tissue; or of small sloughs, or even of an inflamed or diseased condition of a subjacent tissue; as, for instance, when a tubercular deposit in that tissue acts as a source of irritation to the mucous membrane.

Andral reduces the forms of those ulcers which are met with in the intestinal canal, to the following:—1. The circular form, remarkable for their great regularity. 2. The oval form, particularly noticed in the ulcerations of Peyer's glands. 3. The linear form, the ulcer appearing as a groove or fissure. 4. The irregular form, the margin being jagged. This latter form occurs most frequently.

Ulcers of mucous membranes, when considered as to their depth, or as to the nature of their surface, present many varieties, from simple erosion to the complete destruction of the mucous tissue. Thus, in some there is merely so much of the surface of the membrane eroded as to prove the existence of a solution of continuity: if the membrane be covered with epithelium, it is also removed by the ulcerative process: if it be a villous membrane, the villi are likewise destroyed. This form is the result of an inflammation of slight extent. It is more frequent in its occurrence than is generally thought, as from its superficial nature it is very apt to be overlooked. The floor of the ulcer may be formed by the mucous corion as above described; but when the ulceration is deeper, so as to destroy the corion, the sub-mucous tissue is the foundation of the ulcer, which varies in colour, consistence, or thickness. Sometimes the muscular tissue forms the bottom of the ulcer: this state is met with in fever and in some severe forms of dysentery; not only is the superincumbent tissue removed in these cases, but that which passed in between the fibres of the muscles is, as it were, dissected out. The muscular tissue being destroyed, the

bottom of the ulcer is formed by the serous coat of the intestine. These cases often terminate in perforation of the intestine, whether by rupture of the delicate serous membrane, or by an extension of the destructive process to it. The probability of the occurrence of perforation depends, not on the extent or long duration of the ulcer, but on the rapidity with which it burrows.

The possibility of the cicatrization of ulcers of mucous membranes has been disputed: recent observations have, however, fully attested the fact of their cicatrizing. The case of the late Professor Beclard, so well known by reason of the celebrity of the distinguished individual who was the subject of it, would alone prove the fact. This able anatomist, at one period of his life, laboured under marked symptoms of gastric inflammation, which yielded to an active treatment and rigid regimen. Some years after, upon the occurrence of his death from a totally different affection, a distinct cicatrix was found in the small curvature of the stomach. Besides this well authenticated case, the testimony of Troillet, Louis, and other pathologists, leaves no longer any doubt on this subject.

The gastro-intestinal mucous membrane is by far the most frequent seat of ulceration. Next in point of frequency are the buccopharyngeal and laryngeal membranes; while the bronchial and urino-genital portions rarely exhibit ulceration.

Nervous tissue. Acute inflammation of the brain is comparatively rare as an idiopathic disease, but is often the result of external violence, in which case it is generally partial or circumscribed. Examples of general cerebritis are not uncommon as one of the complications of fever; on examination the brain presents general vascularity, but the congestion is greater in the arteries than in the veins; when the blood is accumulated chiefly in the veins and sinuses, it indicates that the lesion partakes more of the character of venous congestion than of inflammation.

On cutting into a portion of inflamed brain, numerous red spots appear, the blood oozing from small vessels, which in the healthy state convey only the colourless part of the blood. The cerebral pulp is at the same time infiltrated with minute effusions or spots of blood, which give it a striated, or when the spots are numerous, a marbled appearance and when in still greater numbers, they form small coagula. These bloody effusions, which may occupy a considerable part of one hemisphere, or only a small portion of the brain, extend more or less in breadth, and give rise to the various shades of redness observed in the section of a portion of inflamed brain, the grey or cortical substance assuming, when inflamed, a dark red or brownish colour, and the medullary a light rose tint.

The highest degree of inflammation which is compatible with the organization of the cerebral tissue is never general, but confined to portions of the brain of various extent, around which the tissue presents the characters of in-

flammation in a more moderate degree. These inflamed portions, which acquire a certain degree of firmness and elasticity, are not exactly circumscribed, but are continued and blended with the surrounding tissue, the traces of inflammation being gradually lost in the healthy structure. In subacute or chronic inflammation of the brain the anatomical appearances are much the same as in the acute, but its duration gives rise to important modifications. The redness soon changes to a crimson, purple, or light brown tint; this change of colour is followed by a diminution in the consistence of the inflamed structure, varying according to the duration of the inflammation, from slight though evident softness of the cerebral tissue to pulpiness, or even semi-fluidity. At the utmost limits of moderate inflammation, a slight though evident softness (*ramollissement*) may be remarked, and only recognized by comparing the softened with the healthy portions of the brain. This incipient stage of softening, which we have repeatedly observed in continued fever, is ascribed by some writers to the infiltration of the inflamed tissue with serous fluid, a supposition rendered extremely probable from the circumstance of the portion of the pia mater which invests the softened pulp being at the same time infiltrated with serum. When the inflammatory action has been still more intense, the structure of the brain is not only softened, but disorganized and infiltrated either with blood or pus. When blood is diffused in the disorganized pulp, it constitutes the *red* softening, in contradistinction to that form in which globules of pus are mixed with the broken-down cerebral mass, which, from the colour it acquires, is termed *yellow* softening of the brain.

The red and yellow softening are sometimes combined in the same morbid mass; blood, pus, and brain being thus blended together, and giving the cerebral tissue a dirty grey appearance, the shade varying according to the proportion in which they are mixed.

There is another kind of softening which, though analogous, differs in many respects from either of the preceding—the *white* softening, in which the cerebral pulp is disorganized and infiltrated with serous fluid. It occurs chiefly in isolated parts of the medullary substance, very often in the corpus callosum, fornix, and septum lucidum. The diseased portions are usually of a pure white colour; but when the cortical substance is affected, it inclines more to a yellow or grey tint. This form of softening is often observed in elderly subjects, and is generally accompanied with serous effusion in other parts of the brain; it is also believed by some pathologists to form one variety of hydrocephalic disease.

Softening of the brain occurs more frequently in the cineritious than in the medullary part, the cineritious substance being from its great vascularity predisposed to inflammation: of the central parts of the brain, it is found more frequently in the septum lucidum, corpora striata, optic thalami, central part of the hemispheres, cerebellum and crura cerebri, and,

according to Dr. Craigie, in the order now enumerated.

There is another alteration of the brain consequent on inflammation—infiltration of the cerebral tissue with pus, which is in some instances diffused in drops through its substance; in others the purulent fluid is confined in distinct cavities of various sizes, the boundary being formed either by the substance of the brain itself, (*undefined cerebral abscess*), or by an organized cyst (*encysted cerebral abscess*).

Though suppuration may take place in any part of the brain, purulent collections are more frequently met with in the hemispheres. They are occasionally the result of acute, but more generally of chronic cerebral inflammation; their progress is slow, and the symptoms, which are always very obscure, vary according to their extent and situation.

Abscesses have been found in the cerebellum by various pathologists, the pus being generally confined in an organized cyst.

Induration has been mentioned as an effect of cerebritis, though some authors deny that it is the result of inflammation or of capillary injection. The fact, however, of its being accompanied with injection of the capillaries, and that the symptoms during life were those observed in chronic inflammation of the brain, are strong presumptive evidence of its inflammatory origin. The induration, which may be general or circumscribed, varies from the consistence of wax to that of cartilage.

Ulceration has been stated to be one of the terminations of inflammation of the brain, and without asserting that this lesion never occurs in the brain, we are inclined to think that some of the older authors have described *softening* as ulceration of this organ. In the cases which bear the greatest analogy to erosion, the ulcerative process appears to have commenced at the convolutions, and to have been connected with circumscribed inflammation of the pia mater.

Gangrene of the brain is very uncommon. It is described by Baillie,* who states that portions of the brain occasionally become gangrenous after violent injuries of the head, but that it is extremely rare when the inflammation arises from any other cause. He mentions one case which had fallen under his observation, in which the mortified part of the brain was of a very dark brown colour, and as soft as the most rotten pear. A similar case, succeeding to injury of the head, is given by Saure,† in which the substance of the brain was black and gangrenous to the depth of three fingers' breadth.

The spinal marrow being similar in structure to the brain, is consequently liable to the same morbid changes; our knowledge of its lesions, however, is more incomplete, less attention having hitherto been paid to their investigation. The various morbid changes which have been described by pathologists originate in inflammation either of the mem-

* Morbid Anatomy.

† Mem. de l'Acad. de Chir. tome i.

branes or substance of the cord; indeed, though the spinal marrow is enveloped with the same coverings as the brain, inflammation is seldom confined to either the membranes or the substance of the cord, but appears to affect both the one and the other at the same time. Those cases, which have been detailed as examples of meningitis of the cord by Abercrombie and other writers, confirm this observation.

In inflammation of the spinal marrow, the membranes and substance of the cord are much injected. The inflammatory action is soon followed by softening of the spinal marrow for a greater or less extent; sometimes the softening is limited to a very small portion: in other cases it extends throughout the greater part of the cord. Blood is sometimes mixed with these softened portions, constituting red softening; and when pus is intermixed, it gives rise to yellow softening. In some instances, the spinal canal contains a quantity of serous fluid, or a layer of puriform fluid is occasionally spread on the membranes, the pus being occasionally mixed with blood, but without apparent softening of the cord. These cases constitute undefined sup-puration or abscess of the cord.

The tissue of nervous cords and their minute filaments becomes occasionally inflamed, and gives rise to a variety of acutely painful sensations. This affection may have a spontaneous origin, but it is more frequently produced by punctured, lacerated, or contused wounds, or by the application of a ligature, as in the common accident of including a nervous twig in tying a bloodvessel for the suppression of hemorrhage or the cure of aneurism. In these cases it is supposed that inflammation is produced in the neurilema or covering of the nerve, which becomes vascular, indurated, and painful. We have an example of spontaneous neuralgia or nerve-ach in sciatica, in tic douloureux, and neuralgia of the median nerve in the arm, and posterior tibial nerve in the leg. These neuralgic affections may also arise from external violence applied in the vicinity of their origin, and of those parts in which they ramify.

Inflammation of nervous tissue may terminate in resolution, in effusion of lymph around the nerve, in ulceration, and in enlargement of the nerve from deposition of new matter. This latter state sometimes succeeds to amputation; the extremities of the nerves become inflamed, and finally much enlarged and indurated—the consequences of chronic inflammation of their neurilema.

Vascular system. Notwithstanding the important share the bloodvessels have in the pathology of inflammation, they are not themselves very often the subject of this action. There is still much difference of opinion among pathologists as to the precise anatomical appearances which should be considered as indicating inflammation of bloodvessels, some attaching no importance to changes in colour and consistence, which others deem impor-

tant lesions and the cause of many serious diseases.

The following are, however, the characters of acute inflammation of a large bloodvessel: redness, rugosity, thickening and softening of its internal membrane, the coagulated blood adhering to it either immediately, or through the intervention of a layer of effused lymph: the middle and outer coats are also injected, thickened, and lacerable, and the consistence of the vessel is so much diminished that it is very easily torn.

1. *Inflammation of arteries.* Though arteritis was considered by Laennec a very rare disease, subsequent investigations have proved that it is not altogether so uncommon as this celebrated pathologist was inclined to believe. The larger arterial trunks have been found more frequently inflamed than the smaller branches; indeed, from the silence of authors on the subject of inflammation in the smaller arteries, it may be concluded that it very seldom occurs.

Arteritis may be either acute or chronic. In acute arteritis the internal membrane is of a bright red colour, and evidently swollen. It is sometimes difficult to determine, whether the redness in the internal membrane of the heart and the larger arteries arises from inflammation, or is the effect of imbibition or staining. When the redness is not accompanied with vascular injection, tumefaction, and alteration of tissue, more particularly when it is circumscribed and terminates abruptly, or appears in patches, it is to be ascribed to imbibition from contact with the blood contained in the artery. When the redness arises from inflammation, the membrane loses its polished and glistening appearance, has a villous aspect, and is easily detached from the other coats. The vasa vasorum also become more numerous and injected, and although it is often difficult to recognize these vessels in the centre of an inflamed membrane, they become clearly developed at its limits. The redness of inflammation differs also from that of imbibition in presenting various tints in the different coats, whereas inflammatory redness preserves the same colour in all. It is, therefore, now agreed that redness of the internal membrane of the heart and arteries, unaccompanied by any other anatomical characters of inflammation, cannot be deemed evidence of arteritis. In inflammation of arteries the redness is accompanied with thickening and swelling of the inner membrane, effusion of lymph either on its free or adherent surface, and increased vascularity with softening of the middle coat, so that the internal and middle tunics present all the ordinary characters of adhesive inflammation. In genuine arteritis, too, the coats are easily detached from each other, and some writers have observed, in intense cases of arterial inflammation, purulent effusion or infiltration between the coats, but more frequently purulent exhalation from the surface of the internal membrane.

Chronic arteritis is also chiefly confined to the

larger arteries, being seldom if ever met with in the smaller arterial tubes. The chief feature of chronic inflammation of the inner membrane of the heart and arteries is redness, but even in recent cases it is more deep than in acute arteritis. When the disease is of long standing, the membrane becomes of a dusky red or brown shade, rugous, and generally softened. These appearances are more remarkable in the vicinity of calcareous, bony, and other morbid deposits, from which circumstance many pathologists have concluded that chronic inflammation is the original source of these organic lesions in arteries. Without attempting to deny the possibility of this origin of these deposits in inflammation, we may remark that their primary formation is not in the inner membrane, but either in the middle coat or in the delicate cellular tissue, which connects the middle to the inner tunic, and that this coat can often be detached from these deposits. Besides, in endeavouring to come to a correct conclusion on this subject, it is to be kept in mind that these various morbid alterations in the arterial coats, whether steatomatous, cartilaginous, calcareous, or bony, form in detached points remote from each other, and without any appearances which indicate the previous existence of inflammatory action. Laennec states that though we know not the nature of the derangement of the economy that produces an ossification or a cancer, it is certainly not the same as that which produces pus. Other writers have endeavoured to clear up the difficulty by supposing that all these morbid changes, which are not the usual products of common inflammation, are the effect of *specific* inflammation; the calcareous deposits, for example, requiring the gouty diathesis for their elaboration; so that, according to this view, every variety of deposition must be the result of a different specific inflammatory action. (See ARTERITIS.) In whatever way these morbid productions are originally formed, the irritation they induce in the arterial coats is evidently a source of chronic arteritis, which may terminate in ulceration.

2. *Inflammation of veins.* This is a more frequent and fatal disease than that of arteries. Though frequent allusions were made to this lesion, the first distinct account was given by the late John Hunter, in a paper in the Transactions of a Society for the Improvement of Medical and Chirurgical Knowledge, in which many of the most important facts connected with inflammation of veins are clearly pointed out. Since the time of Hunter, many valuable contributions have been made to this department of pathology by Meckel, Breschet, Bouillaud, Velpeau, Dance, Ribes, Hodgson, Davis, Trauers, Arnot, and Lee.

The anatomical characters of an inflamed vein are, uniform redness more or less deep, with swelling and pulpiness of the inner coat, which is easily detached from the middle tunic. The redness and swelling soon extend to the middle and outer coats, so that the vein feels hard and contracted, resembling a deep red cord,

imbedded in its cellular sheath, which is generally infiltrated with bloody serum.

The canal of the inflamed vein is filled with coagula of blood often mixed with pus, or a false membrane adheres to the inner membrane, filling its cavity completely, and rendering the vessel an impervious cord.

When a vein becomes inflamed after a wound or puncture, the inflammation sometimes extends along its inner or lining membrane to the principal venous trunks, and occasionally to the membrane which lines the cavities of the heart. From the facts adduced by Mr. Arnot, it appears that there are considerable differences in the extent of vein occupied by inflammation in phlebitis. In some instances the inflammation is limited to the vessel in which it originally appeared; in others it is found to have spread into several or most of the veins of a limb, from that primarily affected. These circumstances, as well as the fact that death has resulted from phlebitis limited to a few inches only, lead to the conclusion that the danger from this disease bears no ratio to the extent of the inflammation of the vein.

The anatomical appearances of an inflamed vein are uniform deep redness of the inner membrane extending over a limited or more extended portion of the vessel. The coats of the vein are generally swollen and indurated, and more easily separated than in the healthy state. The dense cellular substance in which the vessel is imbedded, is at the same time injected and infiltrated with bloody serum. The cavity of the vein is filled with coagula, with which purulent matter is occasionally blended, and its diameter contracted or often obliterated by false membranes which adhere to the surface of the inner coat, and thus render the vessel a hard impervious cord. In fourteen cases out of nineteen, Mr. Arnot found pus, or pus mixed with lymph, in the cavity of the vein; in two the contents are described as consisting of "adhesive matter," and in another the vena cava contained "flakes of lymph." In one case, described by Mr. Hodgson, in which the inflammation occurred in a vein previously diseased, neither pus nor lymph was found in the vessel.

The characters of chronic inflammation of veins differ little from the acute. The redness is of a more deep brown or violet tint, and the coats more thick, so that when the vein is cut across, it preserves its cylindrical form like an artery. The contents of the vein are similar to those described in acute inflammation.

Ulceration occurs more frequently in the larger arterial trunks than in the veins. We have already noticed ulceration of the internal membrane of the heart as an occasional consequence of inflammation. In arteries, the ulceration may be confined to the internal tunic alone, or it may extend to and destroy the muscular coat, so that the blood escapes through the erosion, and, distending the external coat, gives rise to the aneurismal dilatation so minutely described by Scarpa, and which indeed, in the opinion of this pathologist, con-

stitutes the true anatomical character of aneurism. In process of time, however, or from violence, the external coat may be lacerated; the blood then escapes into the cellular sheath in which the artery is enveloped, and thus a true aneurismal tumour is formed.

When ulceration of the larger veins has been observed, it has apparently commenced in the internal lining membrane, and gradually extended to the other coats. The vein has sometimes formed an attachment to some adjoining hollow viscus, the tissue of which becomes also destroyed by ulcerative absorption, and the blood thus escapes into its cavity.

Bloodvessels may be said to be insusceptible of gangrenous inflammation, as they escape the general destruction of the tissues in mortification and sphacelus. It is extremely doubtful if the tissue of the heart be ever affected with gangrene, the cases mentioned by Senac, Portal, and Corvisart, in which gangrenous spots were seen on the surface of the heart, being too vaguely described to be admitted as examples of this lesion.

The tissue of arteries seems to have great power in resisting mortification. Dr. Thomson states that he has seen instances of phlegmonous erysipelas, in which several inches of the femoral artery were laid completely bare by the gangrene, ulceration, and sphacelus of the parts covering it, without its giving way before death. The arteries had the appearance of raw flesh, and were obviously thicker and more vascular than natural, the blood circulating through them, and assisting in supplying with nourishment the parts on which they were distributed. When gangrenous inflammation has been so severe that it extends to the bloodvessels, it has been observed that hemorrhage does not take place, either when the vessel is divided, as in amputation of the limb, or when the limb has dropped off. The blood is prevented from escaping in those cases partly by the extension of adhesive inflammation, which occurs in the line of separation between the dead and the living parts, to the bloodvessels of the limbs, so that their surfaces are pressed together, and adhere more or less completely, and partly also by the coagulation of blood in the extremity of the vessels. This filling-up of an artery by coagulated blood happens, Dr. Thomson conceives, by the closure, by adhesive inflammation, of the small branches going off from the trunk, and by the disposition which is given to the blood to coagulate, in consequence of the secretion of coagulable lymph on the inner surface of the inflamed vessel.

Inflammation of the lymphatic vessels.—This system of vessels is not unfrequently inflamed; and, according to Bichat, inflammation occurs more frequently in the absorbents than in the veins. This assertion is corroborated, when we reflect that the absorbents are constantly exposed to irritation from wounds, punctures, and the introduction of morbid poisons into the system through the external surfaces. Though inflammation of the absorbents is by no means a rare disease,

it seldom proves fatal, the inflammation generally terminating in resolution. In those cases in which an opportunity has been afforded of examining an inflamed absorbent, its coats have been found swollen and indurated, and a layer of plastic lymph adhering to its inner membrane. The cellular tissue surrounding the inflamed vessel is involved in the inflammatory action, denoted during life by a red line, which is exquisitely painful, and after death by induration and serous infiltration.

Andral has examined the thoracic duct and lymphatic vessels in upwards of six hundred subjects, and found but in a very few instances any appreciable alteration of the thoracic duct. In three cases only its parietes appeared red and injected; and in one of these the interior of the duct was filled with pus, and its coats were thickened and friable. In the case of a woman, who died at La Charité, with cancer of the uterus, the thoracic duct, which was considerably enlarged, and of a dead white colour, was filled with a puriform fluid, and its internal surface studded with an infinite number of round white bodies about the size of peas; in the intervals between which the parietes of the duct were thickened, and of a dead white colour, traversed here and there by reddish lines, and in other points they were reduced to a soft pulp of a dirty reddish white. The left subclavian vein, into which the duct opened freely, was distended by a number of dense firm clots of blood firmly adhering to the coats of the vein, the inner surface of which was wrinkled, and of a deep brown colour. This affection of the thoracic duct and subclavian vein evidently originated in inflammation. Andral has occasionally met with the same morbid changes in the lymphatic vessels.

Inflammation of the lymphatic ganglions is more common than that of the lymphatic vessels. Those ganglions are composed of two distinct tissues,—lymphatic vessels variously convoluted, and cellular tissue, by which these convolutions or ganglions are united. These distinct structures may be demonstrated in the human subject by anatomical injection and nice dissection, and the various diseases to which these ganglions are liable originate in one or other of those two anatomical elements. Inflammation of the lymphatic ganglions, which may be propagated from the lymphatic vessels, or arise primarily in the ganglions, is characterized by redness and swelling. The inflammation may be confined to one ganglion, or it may extend to several. The enlargement apparently arises from tumefaction of the cellular tissue, which unites the convolutions of the lymphatics, or from thickening of their coats, as a mercurial injection passes freely through all the convolutions of an inflamed lymphatic ganglion, proving that their cavity is still pervious.

When an inflamed ganglion is cut into, a number of small brownish red points are seen on the divided surfaces; these are exudations from the divided bloodvessels, which have become diffused in the red substance

of the inflamed ganglion. When the inflammation is more intense, the consistence of the ganglion becomes of a dark violet colour, spongy and soft, and often mixed with blood.

When the inflammation terminates in supuration, the pus may be infiltrated in cellular tissue connecting the convolutions, or in the structure of the ganglion, giving it a dirty grey or ash colour. In other cases an abscess forms, so that all traces of its parenchymatous structure are lost, the cellular envelope of the ganglion alone remaining and forming a cyst to the abscess.

When lymphatic ganglions are affected with chronic inflammation, the swelling and hardness are greater than when the inflammation is more acute. The cellular tissue, in which they are enveloped, becomes also inflamed, and forms a dense capsule around the ganglion. Lymphatic ganglions may enlarge in groups, as when the mesenteric glands become enlarged from follicular ulceration, or in chronic non-suppurating buboes of the axilla or groin. When an incision is made into a ganglion affected with chronic inflammation, it presents a dense homogeneous structure of a brown red colour, the vessels with which it is traversed being increased in number, tortuous and dilated, ramifying in all directions, and interspersed with white cellular filaments.

Chronic inflammation of lymphatic ganglions seldom terminates in supuration unless acute inflammation supervene. The pus in these cases is infiltrated in the cellular tissue covering the inflamed ganglion.

Inflammation of muscular tissue. From the comparatively few opportunities of examining inflamed muscular tissue in the human subject, it has been necessary to institute experiments on the lower animals, with the view of ascertaining the appearances this tissue presents when inflamed. The muscular tissue itself does not seem to assume readily inflammatory action; at least inflammation does not leave any well-marked traces of its existence. The principal alteration appears to take place in the intermuscular cellular tissue, which becomes red from increase in the number and size of its bloodvessels; the muscular fibres are at the same time somewhat increased in density, while the contractility, and consequently the power of motion, is more or less impaired, according to the degree and duration of the inflammation.

Gendrin states that if a portion of the centre of a long muscle be once inflamed, its extremities alone retain the contractile power, the middle or inflamed part remaining quite motionless, although the nerve which supplies the muscle is irritated, or even when it is subjected to the influence of galvanism. As the inflammation advances in duration or intensity, the cellular tissue which enters into the composition of the muscle, as well as that which connects it to the surrounding parts, becomes swollen and infiltrated with serosity, with which a portion of coagulable lymph is generally mixed, whereby its density is not only increased, but the muscular tissue so firmly

bound and interwoven, that it is difficult to separate the two tissues, and when this is effected by dissection, the muscular tissue appears sensibly swollen, and of a more or less deep red colour. When the inflammation is intense, the cellular as well as the muscular tissue assumes a deep red or violet colour, and traces of commencing disorganization are perceptible, the muscle and its connecting cellular membrane becoming softened and infiltrated with blood. Suppuration finally takes place, the pus being diffused both in the cellular tissue which surrounds, and in that which enters into the composition of the muscle. The muscular substance becomes finally completely disorganized, and often sloughs extensively; or it is converted into a grey indurated mass, in which irregular cavities form, containing a dirty serosity or ill-conditioned pus.

It appears too from repeated experiments, that when the muscular tissue is destroyed, it is never regenerated; the lesion being repaired by the formation of a cellular or fibrous web which fills up the vacant space. There are several instances of chronic suppurative inflammation in muscle on record, the best example of which is inflammation of the *psaos* muscle, of which Schoenmezel* has given a case in which the whole of the *psaos magnus*, and *iliacus* of the right side was destroyed and converted into purulent matter, forming a sac which extended from the last lumbar vertebra along the surface of the ileum to the small trochanter.

Inflammation of the muscular tissue of the heart is acknowledged to be a very rare affection, and according to the testimony of Baillie and Laennec, when it does happen, it is never a primary disease, but the consequence of extension of inflammation of the pericardium to the muscular structure of the heart. Though cases of genuine carditis are confessedly rare, the probability of its occurrence is placed beyond doubt by the instances which have been recorded; the most satisfactory we have met with is that related by Mr. Stanley,† in which the inflammation was general throughout the tissue of the heart.

The most unequivocal proof, however, of true carditis is when the inflammation terminates in suppuration. In these cases the inflammation is partial, and confined to those portions of the cardiac tissue in which the pus is deposited. The abscess is unencircumscribed, the purulent matter being infiltrated in the cellular membrane which connects its muscular fibres.

Ulcers of the heart have been found both on its external and internal surface, though this lesion also has been very rarely observed. The only case Laennec ever met with occurred on the internal surface of the left ventricle; it was an inch long, and half an inch wide, and more than four lines deep in the centre. This ventricle, which was at the same time in a state

* De musculis psoa et iliaco suppuratis, Heidelbergæ, 1776.

† Med. Chir. Trans., vol. 7.

of hypertrophy, ultimately ruptured. The patient survived only two days.

Inflammation of the tongue (*glossitis*) is a very formidable disease, whether we regard its effects on respiration or deglutition. The organ, when inflamed, becomes swollen, of a vivid red colour, and very painful; as the inflammation proceeds, the swelling increases often to such a degree, that the tongue is thrust out of the mouth, and by its pressure on the larynx impedes both respiration and deglutition. The inflammation may terminate in resolution, suppuration, or even gangrene. The first is the more frequent result, which the practice of making deep incisions into the inflamed tongue tends greatly to promote. When suppuration takes place, the abscess is sometimes superficial, so that it points, and may be opened by an incision. In other instances it is deep-seated, and from the increased swelling there is so great hazard of suffocation, that, if deep incisions made into the tongue do not reach the abscess, it may become necessary to open the windpipe to save the patient's life—an operation which has been repeatedly performed with success in such cases. Gangrene is a rare termination of glossitis, and is indicated by the dark livid colour of the tongue, and the gangrenous odour from the mouth. (See *GLOSSITIS*.)

The uterus being a muscular organ, is liable to the effects of inflammation of this tissue. Uterine inflammation is generally partial, occupying particularly the fundus and posterior part of the organ, and is almost invariably accompanied with inflammation of that portion of the peritoneum which covers its fundus. Its vessels are at the same time gorged with blood; the internal membrane of the organ is of a violet red colour, the injection of the muscular substance giving it a vermilion red or livid hue, according to the duration of the disease; and when blood is extravasated, the portion of the tissue in which this takes place appears marbled, and of a soft spongy consistence. In the more advanced stage of uterine inflammation pus is infiltrated through its substance, and is generally found at the same time in the uterine veins.

Ulceration is another effect of inflammation of muscular tissue. This is sometimes observed in deep ulcers of the extremities, which corrode in succession the skin, cellular membrane, fascia, and ultimately the muscular tissue. It is also observed in the tongue in idiopathic inflammation of this organ, or when it arises from the use of mercury. We have already seen that ulceration occasionally takes place in the heart, and chronic ulceration of the cervix of the uterus is familiar to every pathologist.

Gangrenous inflammation of muscular tissue occurs in the external muscles, as well as in internal organs which have a muscular formation. This lesion is recognized by the black or green colour of the muscular fibres, which are very soft and easily torn, and by the peculiar gangrenous odour of the sphacelated part. When gangrene occurs in an external muscle, the sphacelated portion may slough off,

and the patient ultimately recover. If the sphacelus be extensive, it generally destroys life. Gangrene of an internal organ is almost invariably fatal.

Fibrous tissue. Bichat included under this term, *tendon, ligament, fascia, aponeurosis*, and *periosteum*, in which arrangement he has been followed by succeeding anatomists. This general arrangement, however, has been disputed by Dr. Craigie, who regards the anatomical structure of those several tissues, as well as the chemical composition of some of them, so essentially distinct as to preclude this general classification. For example, the structure of tendon differs from that of ligament and periosteum in being united in regular parallel fibres, and having greater tenacity—the fibres in the latter crossing in all directions, and consequently being with difficulty separated. Inflammation of fibrous tissue is attended with the ordinary effects of inflammation, but it rarely if ever terminates in suppuration or ulceration. We shall examine the effects of inflammation in individual fibrous tissues.

In inflammation of tendon, the natural polished glistening appearance is lost, and is succeeded by faint redness; when it is more violent, this injection is accompanied by softness or pulpliness of its texture, and as the inflammation proceeds, the redness gradually passes into a leaden grey colour; the tissue of the tendon becomes subsequently much thickened, and of a doughy consistence, indicating that its vitality is lost. These changes in inflamed tendon are frequently observed in common whitlow, and in severe injuries of the extremities accompanied with laceration, but particularly in gunshot wounds.

The structure of ligament, periosteum, and fascia, especially that of the two first, is exceedingly similar. The minute filaments of which it consists are so interwoven in various directions, as to form one of the strongest and most compact tissues of the body. It is very sparingly supplied with bloodvessels, nerves, and absorbents. Inflammation of the capsular ligaments of the larger joints, or of the funicular ligaments, as, for example, the lateral ligaments of the elbow, wrist, knee, or ankle-joints, may arise spontaneously, from external injury, or from extension of inflammation of the synovial membrane or articular cartilages to the ligaments. When the inflammation is spontaneous, it is generally of a more chronic kind than when it arises from other causes. Inflammation of ligamentous tissue is speedily followed by thickening of its structure; the inflammatory action is seldom limited, but spreads to the synovial membrane and surrounding cellular tissue, giving rise to effusion into the cavity of the joint, and swelling of its external tissue, which not unfrequently terminates in the formation of superficial abscesses.

Ligamentous inflammation may terminate in resolution or in ulceration, of which latter we have an example in strumous disease of the hip-joint, in which not only a portion of the capsular ligament, but the round ligament

which connects the femur to the acetabulum, is destroyed by the ulcerative process.

Inflammation of the periosteum (periostitis) differs little in anatomical characters from that of ligament. It is never confined to this tissue, but extends to the cellular tissue by which it is connected to the skin and subjacent bone, and from which it is easily separated. A perceptible tumour is thus formed, which is hot and painful, and when examined, is found to consist of injected cellular and periosteal tissue infiltrated with serum or lymph.

Periosteal inflammation may be limited, or it may spread over a considerable extent. When it is limited to a small spot, it constitutes the swelling termed *node*, which forms more readily in some situations than in others, more particularly on the tibia, radius, ulna, clavicle, and sternum. Nodes are sometimes converted into bony swellings (*exostosis*), the lymph which is effused being mixed with calcareous matter. Periostitis sometimes terminates in suppuration and abscess, in which case the skin and cellular membrane over the diseased periosteum become red, swollen, and very painful; fluctuation is perceptible, and when the abscess is punctured, or bursts spontaneously, the corresponding portion of the bone is generally destroyed by caries. Some cases of periostitis are merely symptomatic of primary inflammation or other disease of the bone, the inflammation having spread from the bone to the periosteum.

Fascia, from its extent and importance in the construction of the body, as well as its being evidently the seat of rheumatism, requires special notice. Dr. Craigie has ably combated the idea that inflammation of the muscular tissue is a cause of rheumatism.

"Independent of the fact that the rheumatic pains occur often round joints in which there are no muscles, the theory is at best only an ingenious assumption, and is not supported by any strong facts or arguments.

"Though rheumatic pain is often referred to muscular parts, it is less frequently so than to joints and parts covered by aponeurotic sheaths and fasciæ. Of 520 cases, Haygarth observed in 388 the rheumatic action to be seated in joints, in 118 in muscular parts, and in 14 wandering, general, or migrating through the limbs. Of 170 cases, in 154 one or more joints were inflamed; in 33 cases both joints and muscles were simultaneously affected; and in some cases only were the muscles affected without the joints.

"Though from these facts Dr. Haygarth infers that acute rheumatism is seated chiefly in the joints, he does not attempt to ascertain the particular texture, in the affection of which the disease consists. It is further manifest that while it is impossible to exclude affection of the muscles entirely, it results that this affection is only secondary. The proof adduced by Dr. Scudamore from pressure of the whole course of a muscle, and grasping its substance during severe rheumatism, to shew that the fleshy part is not the seat of complaint, is entitled to attention. Combined with those

already mentioned, and with other considerations to be adduced immediately, it results that the rheumatic action is seated in a texture, which, confined neither to the site of the joints nor to that of the muscles exclusively, is common to both, and which, from its extensive distribution and complicated arrangement, accords best with the phenomena, progress, and effects of the disease. It is unnecessary to repeat the considerations above adduced from the anatomical relations and characters of fascia and its various divisions. That they are the chief seat of acute rheumatism may be inferred from the following circumstances.

"1. When the rheumatic action is seated in muscular parts, instead of being confined to the muscular fibres, it may always be referred to the aponeurotic membrane which covers or penetrates them. 2. The peculiar pains of rheumatism are always most distinct in those situations in which several folds of aponeurotic membranes meet; and their migrations may be traced from one extremity to another of aponeurotic membrane, and along the course of its principal divisions. 3. The kind of pain which attends rheumatism resembles that of the fibrous tissues in general when inflamed, in undergoing aggravation under the influence of external heat, and during the night. 4. This view of the seat of rheumatic disorder affords the most probable explanation of the effusion which takes place in the tendinous sheaths (*bursæ mucosæ*); for since each sheath is partly enveloped in aponeurotic membrane, the inflammatory process which takes place in the latter soon gives rise, as in analogous cases, to effusion, critical or non-critical, from the contiguous synovial membrane. 5. This view also affords the most rational explanation of the fact remarked by all authors, that rheumatism almost never terminates in suppuration. To suppose that muscle does not suppurate is, perhaps, erroneous, from what has been above adduced. That fascia and fibrous tissue in general is little disposed to suppurate, unless when mechanically injured, is manifest from a number of circumstances; and this may, perhaps, be regarded as the true explanation of the fact now noticed. 6. It must further be remarked that inflammation in this tissue renders it thick, hard, and rigid; and occasionally causes between its fibres effusion of lymph, which increases this thickening, induration, and rigidity. On these changes depend the immobility of rheumatic parts, and the loss of power which follows long and obstinate, or neglected and repeated attacks of the disease.

"The question whether there be any thing peculiar in the nature of rheumatic inflammation is not undeserving attention. This, however, is not the place for discussing it; and if the views now advanced be well-founded, it may be inferred that its peculiarities consist in the anatomical and physical qualities of the texture in which I have attempted to shew it is seated.

"Though in acute rheumatism the inflamma-

tion affects a large proportion, if not the whole, of the fascial system, local forms of the disease may occur, in which it is confined, with more or less accuracy, to one or two fasciæ. Thus inflammation of the fascia of the temporal and masseter muscles produces rheumatism of the temple and rheumatic locked jaw; that of the occipito-frontal fascia, rheumatism of the head; that of the cervical fascia, crick in the neck; that of the pectoral fascia and the intersections of the intercostal muscles, spurious pleurisy (*pleurodyne*); that of the abdominal fascia, a rheumatic bellyach; that of the lumbar fascia, *lumbago*; and that of the aponeurotic parts of the gluteal muscles, genuine *sciatica* or hip-gout.*

Inflammation of cartilage, which is generally of a chronic character, may take place as a primary disease; but it more generally succeeds to synovial inflammation. It is characterised by redness, spongy swelling, softness, and finally ulceration or erosion of its structure. Erosion, which in cartilage is analogous to caries in bone, consists first in minute perforations, which extend in number and depth, and, by their coalescence, form patches of an irregular size and shape. When the erosion extends in depth, the epiphysis of the bone is exposed, excavations form, and sometimes the cartilage is entirely removed. The joint is thus destroyed, unless, as in some cases, *ankylosis* take place.

We have another instance of inflammation and ulceration of cartilage in the larynx, in which the inflammation may either take place primarily, or it may spread from the mucous membrane of the throat to the perichondrium or investing membrane. The disease in these cases is generally chronic, even at its commencement; and, though it may arise from cold, it is more generally to be traced to the effect of a specific poison—the syphilitic or the mercurial. It often succeeds to the development and subsequent disorganization of tubercular formations in the structure of the larynx, giving rise to the disease termed *phthisis laryngea*. Both these differ essentially from the more acute and rapidly fatal forms of laryngitis, which consist in acute inflammation and infiltration of the submucous cellular tissue of the glottis.

Fibro-cartilaginous tissue is regarded as intermediate between the fibrous and cartilaginous, possessing the flexibility and elasticity of the former, with the toughness and resistance of the latter. The intervertebral substance of the vertebræ, the semilunar cartilages of the knee-joints, and the cartilages which unite the pelvic bones, are composed of this tissue. These parts are liable to inflammation, which may either originate in their own substance, but more generally in the surrounding structure, or in the synovial membrane with which they are in most instances invested. The inflammation in fibro-cartilaginous tissue produces swelling and softening, which frequently terminates in erosion, as we occasionally ob-

serve after inflammation of the semilunar cartilages of the knee-joint and of intervertebral substance.

Mortification may take place in fibrous tissue. When this occurs, its glistening appearance is lost, and changed to an ash-grey colour, while its texture becomes softened and easily torn. It may even become completely dead or sphacelated, as in sloughing of the cornea, or when large portions of the soft parts, or even an entire limb has been removed by idiopathic gangrene: in these cases the fibrous tissue sloughs with the other structures of the mortified limb.

Bone. The structure of bone undergoes the process of inflammation, which is the origin of many of those diseases to which the osseous system is liable. It may arise spontaneously, or from various kinds of injuries. The process by which the extremities of fractured bones are united, and the erosion which takes place when the epiphyses become separated, are examples of the adhesive inflammation of bone. The bony union by which these injuries are repaired is effected by the blood which oozes from the periosteal and medullary arteries, and the subsequent elaboration of coagulable lymph into which new vessels penetrate, so that the lymph becomes an organised substance similar to granulation, and is termed *callus*. Upon this new substance points of bone are deposited by a peculiar and hitherto unexplained action of the nutrient vessels; these points of bone become gradually more numerous, and finally coalesce into larger masses, until the fractured extremities are at length united by solid bone.

Idiopathic inflammation of bone may arise either in the periosteal covering, or in the cancelli, or medullary structure. We have already explained the effects of inflammation of the periosteum in producing those swellings called nodes: when the periosteal inflammation is very acute, it produces not only thickening of the membrane and deposition into the subjacent cellular tissue, but inflammation of the portion of bone with which it is in contact. If the inflammation be not promptly arrested, suppurative inflammation of the periosteum, followed by caries or ulceration of the bone, succeeds, which often penetrates the substance of the bone to a considerable depth.

Another form of osseous inflammation is that arising in the filamentous medullary structure of long bones, producing swelling and effusion into the cancelli, which may terminate either in permanent induration and enlargement of the bone, or in suppuration. When suppurative inflammation thus takes place, the matter is sometimes deposited in the cavity of the bone, and generally proves a source of great constitutional disturbance. In other cases the vitality of the bone is gradually destroyed from within outwards, constituting the disease termed *necrosis* by surgical writers. This may affect either a part or the whole of the shaft of the bone; so that the epiphyses and periosteum, which are seldom affected, only remain. In the progress of the disease

* Op. cit. p. 515.

the dead portions are enclosed in a case of newly-formed bone, and covered with thickened periosteum.

The two diseases termed *caries* and *necrosis* afford an illustration of ulceration and gangrene of bone. In necrosis, however, reparation is effected by the formation of a new envelopment around the mortified or dead bone. In superficial gangrene of the long bones, such reparation is not observed; these latter cases, therefore, have a greater affinity to gangrene of soft parts.

Inflammation of the medullary texture of the epiphyses, and of the short or cuboid bones, such as the vertebral, tarsal, carpal, and digital, is the cause of the disease described by surgical writers under the term *spina ventosa*.

Dr. Craigie states that the cancellated arrangement of the osseous matter and of its medullary web in these bones, explains the progress and phenomena of the disorder. That this is the seat of its action is to be inferred, first, from the phenomena of the disease; and, secondly, from its effects as seen in diseased bones. *Spina ventosa* never occurs in a bone with distinct medullary canal, unless at the epiphyses, where the structure is cancellated. When it takes place in these situations, it first induces an enlargement of the epiphyses, with extreme deep-seated pain in the bone. Soon after the periosteum becomes thick and swelled; and in no long time sanious matter is found beneath it issuing from the cancelli, which are then softened, partially destroyed, and excavated. If in this state such a bone be examined, the broken cancelli are filled with a reddish, soft, spongy, vascular mass, producing flabby granulations *passim*, and secreting bloody sanious fluid. The compact shell is partly destroyed by irregular ulceration, and partly extruded by the distending force of the swelled medullary web. The diseased epiphysis then presents a large irregular anfractuous cavern, filled with soft spongy substance, which is either the web itself, or the new products which its inflammation has generated. In this manner it is frequent in the upper end of the tibia or the lower end of the femur, or in the extremities of the radius or ulna. (*Op. cit.*)

The effects of inflammation in the different tissues having been briefly considered, it is necessary to shew the changes induced by inflammation in organs which are composed of several tissues (*complex tissues*). The structure of the lungs is, of all the organs in the body, the most complex: it consists of arteries, veins, absorbents, nerves, and the ramifications of the bronchial tubes, lined with mucous membrane, and terminating in very small round cells; all these component parts being firmly united by cellular tissue. It is necessary to be able to distinguish congestion from inflammation of the pulmonary substance, as there is certainly no organ in the body so frequently the seat of congestion. We find very generally, on examining the lungs, even when the person dies in an exhausted state, as in continued fever for example, that the most depending portions are in a state

of congestion. This is owing to the blood gravitating from the position of the body after death. This appearance, though often mistaken for the effect of inflammation, is a pseudo-morbid appearance. It is frequently found in cases where there has been a severe and protracted struggle previous to dissolution, or where there has been a mechanical obstruction to the circulation produced by some organic disease of the heart.

The anatomical characters of inflammation of the substance of the lungs (*pneumonia*) differ according to its stage or degree. Laennec has described three stages, which he considers may be easily recognized; these he has distinguished by the terms *obstruction* (*engouement*), *hepatization*, and *purulent infiltration*, all of which present different anatomical characters.

In the first degree (*engouement*, or *obstruction*) the portion of inflamed lung is externally of a livid or violet colour, which is not removed by immersion in water, or even injecting water into the pulmonary vessels, and more heavy and dense than natural. When pressed between the fingers it is still crepitous, though less so than in its sound state, retaining the impression of the finger like an œdematous limb. It is necessary, however, to bear in mind that lungs which possess naturally a considerable degree of density have proportionally less crepitation. This density of the pulmonary tissue is more remarkable in children. When cut into, the structure is of a dark red colour, the tissue being filled with a serous fluid, more or less tinged with blood; but though evidently injected, the natural soft spongy texture is unaltered, and still permeable to air.

In a more advanced stage of pulmonary inflammation, the smaller bronchia, air-cells, and connecting cellular membrane, become swollen, so that the quantity of air in the inflamed portion of lung is diminished and supplied by blood. This constitutes the second degree of pneumonia (*hepatization*). It is characterized by a deep red colour of the inflamed portion of the lung, varying in different points from that of violet grey to blood red, and by the greater density and consistence of the granulated texture exhibited in its section, giving it somewhat the appearance of liver, from which the term hepatization has been derived. The hepatized portion of lung has lost its crepitous feel, is impermeable to the air, and sinks in water, and when divided, no air escapes, but a small quantity of bloody serum, mixed with a thick opaque fluid, may be expressed. When the minute structure is examined closely, the natural pulmonary texture has lost its cellular appearance, and appears to be composed of a number of small red grains, oblong and flattened, which, according to Laennec, are the air-cells transformed into solid grains by the thickening of their parietes, and the obliteration of their cavities by a concrete fluid. Andral, however, states that this granular appearance is often altogether wanting, so that its surface, when cut into, appears smooth and compact. He supposes the granular appearance to depend on the degree of tumefaction which the air-cells un-

dergo; for when the tumefaction passes a certain limit, its effect is to approximate the cells so closely that they become confounded together, and the granular appearance vanishes entirely.

The extent of pulmonary substance occupied by these two degrees of inflammation is various. Sometimes the inflammation extends over an entire lobe, (*pneumonia lobaris*): in other instances it is confined to one or more lobules (*pneumonia lobularis*): in some cases it affects only the air-cells (*pneumonia vesicularis*): some writers indeed consider that in pneumonia the inflammation commences in the air-cells, from which it is propagated to the parenchymatous tissue.

When pulmonary inflammation has advanced to the formation of pus, this fluid is found either in the form of purulent infiltration, or collected into an abscess. Purulent infiltration is by far the more common appearance; this succeeds to the most intense degree of pulmonary inflammation, and often takes place with great rapidity. According to Andral it has formed within four days after the first symptoms of pneumonia had made their appearance. The portion of lung in which the purulent infiltration has taken place presents an ash-grey colour, from which it has been termed *grey hepatization*, to distinguish it from the second stage of pneumonia, the *red hepatization*. If the pus be squeezed from the pulmonary texture, it assumes the colour of the red hepatization, but it is much softened and consequently easily lacerated. The grey colour is evidently owing to the admixture of pus with the red tissue of the inflamed lung.

These three stages of pulmonary inflammation may be often seen in different portions of the same lung; sometimes an entire lung is infiltrated with pus, while the other presents different stages of pneumonia; some portions being in a state of red, others of grey hepatization, the one stage passing by insensible degrees into the other.

With regard to the portion of lung most frequently affected with pneumonia, it appears from the statements of Laennec, Andral, and others, that it occurs most generally in the lower portions, though it is not uncommon to meet with a circumscribed portion of the centre of the lung inflamed, the surrounding parenchyma being quite sound.

It is a singular circumstance, also, that the left lung should be much more frequently the seat of pneumonia, and, indeed, of almost every lesion, than the right. Of two hundred and four cases of evident pneumonia, the right lung was affected in one hundred and twenty-one instances, the left lung in fifty-eight, and both lungs in twenty-five.*

Abscess of the lung has been very rarely met with, though cases succeeding to pneumonia are recorded by several writers. In these instances the boundary of the excavation in the lung, which is filled with pus, is formed by the pulmonary tissue.

Another and perhaps more frequent form

of pulmonary abscess is that in which pus is deposited in the lung, not as the consequence of inflammation, but from this fluid, formed in some other part, being conveyed through the medium of the circulation, and deposited in the lung. There are many striking instances of these purulent deposits succeeding to important operations, and to purulent collections in other organs of the body, which, after an attentive examination, Andral proposes to range in two classes. In one, it appears that the pus is formed in the torrent of the circulation, or is introduced into it from some organ in a state of suppuration, and in its passage through the tissue of the lung is separated as through a filter, and either collected into an abscess, or infiltrates the pulmonary tissue. It is probably by a similar process that mercury injected into the crural vein of a dog traverses the whole circulating system until it arrives at the lung, where it abandons the circulating fluid. In the other class of cases, some cause with which we are unacquainted alters the blood, coagulates it in the pulmonary vessels, and transforms it into purulent matter in the smaller branches of these vessels.*

The termination of inflammation of the lungs in gangrene is exceedingly rare, and when it is met with, it is not always to be regarded as an indication of the intensity of the pneumonia, as it has been found in cases when the symptoms, as well as the appearances of inflammation, were very slight and equivocal. Laennec regards it as very similar to idiopathic gangrene, such as anthrax, pestilential bubo, and malignant pustule. Andral, on the other hand, asserts that gangrene of the lung, as well as of other parts of the body, may succeed to every species of hyperæmia, whether mechanical or vital, provided it be so considerable as to impede or prevent the afflux of arterial blood to the part.

Gangrene of the lung occurs under two forms—the *circumscribed*—and the *uncircumscribed*; the one differing from the other only in extent.

Circumscribed pulmonary gangrene occurs in a small portion of the lungs only; the mortified part is separated by a suppurative process which is established around it, and the eschar or slough is expelled with the expectoration through perforation of one or more of the bronchial tubes. An ulcerous excavation discharging a dirty fluid remains, which, by mixing with the expectoration, gives it a most offensive odour. When the gangrene occurs near the surface of the lung, it produces erosion of the pleura, which is succeeded by pleurisy and pneumothorax.

Uncircumscribed pulmonary gangrene is much less common than the circumscribed. Laennec had only seen two cases of it during twenty-four years, and he had only known of five or six cases of it in the hospitals at Paris during the same period. He gives the following characters of this lesion, which may occupy a great portion of one lobe, or occasionally

* Andral, Clin. Med. tom. ii.

* Anat. Patholog. tom. ii.

the greatest part of one lung. The pulmonary tissue, more humid and less cohesive than in the sound state, has the same degree of density as in the first state of peripneumony, œdema of the lungs, or the serous engorgement occurring after death; its colour varies from a dirty white or slightly greenish hue, to a deep green, approaching to black, with a mixture, occasionally, of brown, or of earthy or yellowish brown. In some places the pulmonary substance, altogether or nearly sound, blends insensibly with the gangrenous part; in other instances, these are separated by a portion of lung inflamed in the first degree, and in still rarer instances by pulmonary hepatization.

Spleen. The spleen consists of few anatomical elements—first, a fibrous investing membrane, constituting its proper capsule of the organ; secondly, an internal cellular arrangement into which the blood is poured; thirdly, bloodvessels, lymphatics, and nerves. As the parenchyma of this organ, therefore, consists of two component ingredients only, fibrous tissue and blood, its diseases must be referable to one or other of these. Andral thinks its diseases ought to be the same as those of the veins, for it is evidently a vast venous network, in which the cellular is substituted for the vascular form. He therefore considers the lesions of the spleen to be of two kinds; those of the first, which are rare and unimportant, have their seat in the capsule, or in its fibrous prolongations, which constitute the walls of the splenic cells; those of the second, of much greater frequency and importance, originate in some of the elements of the blood.

The capsule of the spleen is liable to the diseases of fibrous tissue, and consequently to inflammation, though such instances are rare. Abercrombie has seen the spleen completely enveloped in a thick dense covering of false membrane, in connection with peritonitis, but without any disease of its substance. In such cases, however, the lymph was probably effused from the inflamed peritoneum, and not by the capsule of the spleen. This membrane has also been found adherent to the contiguous viscera in cases of purulent infiltration, when the pus is making its way towards the surface of the spleen, and if the organ to which it becomes attached be hollow, (as the stomach or alimentary canal,) the matter is discharged into it. The capsule of the spleen has been found in many of those instances soft, pulpy, and lacerable.

Cases of purulent formations in the spleen are not very common, more especially those in which pus is found in no other organ. It is improbable that such instances originate in inflammation of its parenchyma, since we have seen that its structure is such that it may be said to be almost insusceptible of inflammatory action, unless the blood be presumed to be susceptible of inflammation. Whence, therefore, originates the pus? This is a question of rather difficult solution, though Andral thinks from some experiments it would seem probable that the blood in the spleen may be converted into pus; and that the disturbance in the system

which has been observed to accompany this lesion, is to be regarded as the result of the conversion of the blood into purulent matter.

A more frequent form of purulent formation in the spleen is when this organ becomes infiltrated with pus, at the same time that similar purulent deposits take place in other organs. In these cases it is supposed that the pus is formed in some distant organ, and after being carried in the blood, is deposited in the spleen and other organs at the same time. In such examples, the primary disease has sometimes occurred in connexion with diseases of the uterus, or of the uterine veins; as in a case recorded in the Transactions of the College of Physicians,* and in another alluded to by Andral:† in other instances, the purulent depositions have succeeded to external injuries and severe surgical operations. The pus may be collected in drops, or in cavities of greater or less extent; it is sometimes confined in a cyst of false membrane, but more frequently the wall of the abscess is formed by the structure of the spleen, in which case the abscess is often of very considerable extent.

The termination of such cases is various: the abscess may, by adhesive inflammation and the subsequent process of ulcerative absorption, burst into the cavity of the chest, belly, stomach, or intestines, or it may be discharged through the kidneys by the urine. Splenic abscesses have been known also to open externally through the walls of the abdomen, the back, or the loins (*Andral*).

Though the thyroid gland is occasionally inflamed, it seems to be as little susceptible of inflammation as any gland in the body. When inflamed, its vessels are numerous and injected, so that its tissue is red and swollen, and feels much firmer than in its natural state; these changes being produced partly by serous infiltration, or when the inflammation is more intense, by the effusion of coagulable lymph or blood into its structure.

From the rare occurrence of inflammation of this gland, its pathological appearances consequent to inflammation, have been scarcely noticed in the writings of pathologists.

Inflammation of glandular organs of secretion. Without entering into the disputes of anatomists, as to the form and texture which are necessary to constitute glandular structure, we shall merely state, that the most perfect glands are the lachrymal, salivary, submaxillary, sublingual, mammary, and prostate—the pancreas and testicle (*colourless glands*), and the liver and kidneys (*coloured glands*). Their external form is generally round or ovoid, and most of them consist of small lobules, connected by cellular tissue. For their size they are the most vascular parts of the body, a large supply of blood being necessary for the purpose of elaborating the various fluids secreted by glands.

When a glandular organ is inflamed, it increases in size, and its excretory ducts become enlarged and distended: the tissue of the colourless glands is of a slight rose tint: in the

* Vol. v. p. 304.

† Anat. Path.

coloured, the natural redness becomes deeper, the injection extending throughout the interlobular cellular membrane. The excretory ducts are filled with fluid which is generally limpid, unless the inflammation be intense, when it becomes red, and even bloody. These anatomical appearances, however, pass off very rapidly after death.

Inflammation of a gland generally terminates in resolution; but if, from its intensity or improper treatment, it proceed to suppuration, the purulent matter forms in the cellular tissue of which the gland is partly composed, the proper substance of glands being not very susceptible of the suppurative process. When, however, the inflammatory action is very intense, it undergoes a species of suppuration; it loses its consistence, and to the softening succeeds infiltration with a thin kind of pus, the sensible qualities of which depend very much on the state of health and particular constitution of the individual.

When suppuration takes place in glands which have large secreting ducts, as the liver and kidneys, the mucous membrane with which these canals are lined sometimes assumes the suppurative action; hence, when pus is mixed with the fluid which the gland secretes, (the bile or urine for example,) it may be secreted either by the inflamed mucous lining of the duct, or there may be a communication between an abscess in the organ and the duct through which the matter is discharged.

These general observations being sufficient to give an idea of the effects of inflammation in glandular organs, we shall, without noticing specially the external glands, make a few remarks on inflammation of the internal organs of secretion—the *pancreas*, *liver*, and *kidney*.

1. The *pancreas* appears to be seldom the subject of inflammation and its consequences; in those cases which have been reported as instances of inflammation of this organ, the symptoms during life were not only very obscure, but the anatomical characters of the lesion not well defined.

In the cases which are reported, redness, more or less deep, and loss of consistence of the substance of this organ, with injection and infiltration of the interlobular cellular membrane, are the morbid appearances described. The inflammation does not appear to have extended through the whole structure of the gland, but limited to one portion of it.

When inflammation of the pancreas has terminated in suppuration, the small lobules of which the pancreas is composed assume a grey-red colour, and become soft, and finally so completely disorganized, as to lose all trace of their original structure. The purulent matter is in some cases diffused through the cellular substance; in other instances the pus is confined in a distinct cavity or cyst, the abscess sometimes forming a tumour of considerable size adhering to the surrounding viscera. Sometimes, again, the pancreas has been found hard and shrivelled in the centre of the purulent deposit. These pancreatic abscesses have been known to make their way across the cellular tissue of the

mesocolon, and, by perforating this membrane, the purulent matter has escaped into the cavity of the abdomen.

2. Congestion of blood may take place in the parenchyma of the *liver*, from causes originating in the organ itself, or as the effect of sympathetic disturbance in some other part. Again, when there is any obstacle to the free return of blood to the right side of the heart, the blood accumulates in the liver, and thus passive hepatic obstruction or congestion is induced. When this takes place, the liver is of a uniform red colour, a little increased in bulk, and evidently changed in density or consistence. Under the pressure of congestion the bloodvessels sometimes give way, and the blood is diffused through its parenchyma, constituting what the French writers term *hepatic apoplexy*. This lesion may be the result of rupture of one or two of the larger hepatic vessels, or of exudation from the capillaries.

Inflammation of the liver is more common in warm than in temperate climates; and notwithstanding the frequency of its occurrence, its anatomical characters are not very distinctly laid down, which may arise from hepatitis being very rarely fatal in the inflammatory stage, so that few opportunities of ascertaining the morbid appearances occur. The appearances in inflammation of the liver differ according to its intensity, duration, and extent. Though inflammation may occur either in the serous covering, or in its parenchyma, it appears to be much more frequent in the latter. Indeed, from the history of hepatitis, given by writers who have had extensive opportunities of observing the disease in hot climates, we are informed that inflammation of the capsule of the liver is of comparatively rare occurrence.

In the milder forms of hepatic inflammation the organ is slightly increased in size and density, and of a dark-red colour, from accumulation of blood, which flows freely where an incision is made. These changes are more evident when the inflammation is circumscribed or partial, as the morbid may be then contrasted with the healthy structure. In the more advanced stage, or when the inflammation has been from the beginning more intense, the parenchyma is more or less softened, and very vascular, the vena portæ, mesenteric vessels, and mucous membrane of the duodenum, being gorged with blood.

The degree to which this hepatic softening occurs depends on the degree and duration of the inflammation. In the more intense cases, the tissue of the liver occupied by the inflammation is reduced to a soft lacerable pulp of a deep violet or brown colour.

When hepatic inflammation terminates in suppuration, the pus may be diffused through the parenchyma of the liver, so as to give it a green-yellow colour, the tissue in which it is infiltrated, and for some extent around, being softened and disorganized. In other instances the pus is confined in abscesses, varying in size, sometimes distinct from each other, but

occasionally communicating by perforations. These abscesses may be bounded by the parenchyma of the liver only, or by a more or less completely organized cyst; they often acquire a very large size, in some instances containing several pints of pus.

The termination of abscess of the liver is various;—1. it may be discharged through an opening in the hypochondrium, or some other situation: 2. when adhesion between the hepatic abscess and some portion of the alimentary canal or kidney takes place, the pus may be discharged by the stomach, bowels, or kidney: 3. the abscess may burst into the cavity of the abdomen: 4. it may perforate the diaphragm and be discharged into the cavity of the chest or pericardium; or if an adhesion form between the hepatic abscess and the lung, the pus may be discharged through a perforation in the bronchial tubes by expectoration. Andral alludes to a case of hepatic abscess situated near the gall-bladder, emptying itself into it, and passing from thence into the biliary duct; and also to a case in which abscess of the liver communicated with the vena cava.

Gangrene of the liver, if it do really occur, must be regarded as an extremely rare termination of hepatitis, as no unequivocal instance of this lesion has been recorded. Mr. Annesley, whose extensive opportunities of observation entitle him to be regarded as an authority, states that he never observed it as a termination of hepatitis of warm climates.

3. Inflammation of the *kidneys* is characterised by obscure redness of the *tubular*, and bright-red colour of the *cortical* substance, the tissue of the former acquiring a degree of firmness, the latter becoming softened, and easily torn.

The emulgent vessels are generally turgid, and the inner membrane of the pelvis and infundibula red and injected, the redness often extending along the membrane of the ureters.

In more intense renal inflammation the tissue of the kidney becomes of a deep red or chocolate colour, and remarkably softened.

Inflammation of the kidney may terminate in resolution, softening, and induration of its parenchyma, or in the formation of pus. Purulent formations in the kidney may take place in three different modes. 1. The inflammation may commence in and be confined to the tubular or secreting portion, and pass into supuration, in which case the uniferous tubes, infundibula, and pelvis of the kidney, secrete purulent matter, which is discharged with the urine. In these cases the kidney is not enlarged in size, and the signs of inflammation are confined to the secreting part of the organ. 2. The pus may be infiltrated through the tissue of the kidney, accompanied with deep-red colour and softening of its substance; a number of white spots, frequently mixed with blood, are seen, from which pus may be squeezed; they are often mistaken for masses of tubercle. This form may be the result of inflammation, or of general purulent diathesis, when pus is found in other organs. 3. The purulent matter may be collected in distinct abscesses. These may

be of small extent, the surrounding parenchyma being scarcely altered; or the whole tissue of the organ may be transformed into a purulent sac, which, according to Andral, is generally multilocular, the septa consisting of hard lardaceous tissue. They may exceed in bulk the kidney itself, and thus produce a tumour distinguishable through the abdominal parietes.

The inflammation in some cases commences in the renal capsule, to which it may be limited, or it may extend to the adjacent portion of the kidney. In these cases suppuration generally follows, but the abscess is exterior to, and unconnected with the substance of the kidney, the structure of which is unaltered, though often, from the pressure of the abscess, diminished in bulk. Abscesses sometimes form in the abundant loose cellular tissue which lies beneath the peritoneum, and surrounds the kidney and its proper capsule. Morgagni gives a case of this kind, which contained four pounds of purulent matter.

Renal abscesses may be discharged in various ways:—1. the pus may pass off with urine; 2. it may burst into the abdominal cavity and produce peritonitis, which is speedily mortal; 3. the abscess may form an adhesion and open into the colon; 4. it may be discharged externally by a perforation in the loins.

Gendrin has quoted a case from Ledran, in which a renal abscess opened at the loins, and the matter having forced its way in the sub-peritoneal cellular tissue down under Poupart's ligament and around the crural vessels, was also discharged at the inner part of the thigh. He alludes also to that case related by De Haen, in which an abscess in the left kidney, after destroying the substance of the organ, formed an adhesion to the diaphragm, which it perforated, and destroyed the inferior lobe of the left lung, the kidney and lung thus forming one large sac.

Causes of inflammation. There are few circumstances connected with pathology more obscure and unsatisfactory than the etiology of diseases. This is fully exemplified in the obscurity in which the origin of almost every form of inflammatory disorder is involved. Many, indeed, arise without evident cause, constituting what has been denominated by practical writers spontaneous inflammation—a term which simply denotes that the causes are so obscure as to elude observation.

It would appear, however, that certain circumstances predispose the system or render it more liable to inflammation; this predisposition may exist either in the system in general, or it may be confined to a particular region, organ, or tissue.

The *predisposing* causes may be arranged in two classes, the first depending on general sanguineous plethora; the second are connected with local determination of blood. Practical writers have usually mentioned the sanguine temperament among the individual causes which predispose to inflammation. Persons who possess this temperament are generally supposed to have a superabundant quantity of blood, whereby the vessels, more especially the

capillaries, are kept in a state of undue distention, the blood having at the same time great consistency or richness. It is also asserted that adults, especially male adults and those possessing what is called a strong constitution, are more predisposed to inflammatory diseases. It has always appeared to us, however, that these views are not supported by facts and observation, and in our own experience, we have generally found that weak and delicate persons are much more frequently attacked with inflammation than the more robust and vigorous. Not less unsupported by evidence is the notion entertained by Van Swieten, that serous evacuations, such as profuse sweating, salivation, or copious flow of urine, predispose the body to inflammation, in consequence of the blood acquiring greater consistency from the abstraction of its watery principles. A predisposition to inflammation, or tendency to particular local determinations of blood, is observed at certain periods of life. We accordingly find that there is a greater tendency to cerebral fulness in infancy and childhood than at other ages; towards puberty, we observe fulness of the pulmonary system, which accounts for the frequency of nasal and pulmonary hemorrhage at this period. In adults, on the other hand, diseases of the abdominal viscera connected with vascular fulness are more common, though it should be kept in mind that congestions or irregular distributions of blood are more common than organic inflammation. It is often of great consequence to discover those circumstances which give a predisposition to inflammation in particular organs and tissues. These may often be traced to a state of partial or local plethora, connected with causes which are inherent in the part itself, though a predisposition to local inflammation is frequently acquired. Thus the undue exercise of an organ frequently predisposes it to inflammation, an illustration of which is the tendency to ophthalmia or retinitis induced by long-continued use of the eye, or straining this organ in examining very minute objects; in the effect of long-continued application to study in producing slow, insidious, cerebral fulness; in the effect of long-continued exposure to cold in laying the foundation of pulmonary diseases; and in the tendency to hepatic inflammation engendered by residence in a warm climate.

It is also a well-known fact that a predisposition to inflammation is given by previous attacks. This is so much a matter of experience and observation that it is scarcely necessary to adduce examples in illustration.

Whatever circumstance or combination of circumstances breaks up the general powers predisposes the body to inflammatory diseases, by rendering it unable to contend against the exciting causes. It is in this way that undue bodily or mental exertion, the depressing passions, long-continued watching, impure air, improper or scanty supply of food, or insufficient clothing, may be regarded as predisposing causes of inflammation.

It is worthy of remark that the predisposing

causes have a considerable influence in determining the type of the subsequent inflammation, as well as the nature and extent of the curative measures. Those inflammatory diseases which arise suddenly, are generally connected with a full habit, and require active treatment; while those which come on more slowly, or in exhausted constitutions, are of the asthenic character, requiring greater circumspection in the nature and extent of antiphlogistic remedies. In such cases we are often obliged to support the general powers, when the local symptoms render the topical and even the general abstraction of blood, among other antiphlogistic measures, expedient.

The exciting causes of inflammation are no less obscure than the predisposing. Many pathologists have expressed their doubts as to the possibility of inflammation ever arising spontaneously. There can be no doubt that in many instances organic inflammation appears without our being able to discover its cause. Thus, inflammation is often set up in the brain, chest, or abdomen, without any evident cause. The inflammation is then termed spontaneous, in contradistinction to accidental inflammations, which are so called from their originating in causes applied immediately to the part affected. It would be unreasonable to say that in such cases the inflammation arose without some cause, though it may not be possible to detect it.

There has been too great disposition, on the part of systematic writers, to take for granted the ordinary list of exciting causes of inflammation. A little reflection will soon convince the patient observer of nature, that the causes of disease are more mysterious than we are led to suppose from perusing systematic treatises. If the etiology of diseases were studied at the bedside, the obscurity of this department of medicine would be apparent; and it has been constantly observed that most idiopathic inflammations are developed by causes which elude our observation.

The effect of atmospheric causes on diseases in general has attracted the notice of physicians from very early ages. Inflammatory disorders are certainly more common in cold, variable, moist weather, and more especially when the wind blows from the north; hence, in the winter and spring, we observe the various types of inflammatory diseases. The mucous membranes seem to suffer more particularly in cold moist weather, and the serous membranes and parenchyma of organs in cold dry weather; while in summer cutaneous inflammations (idiopathic or secondary) are observed to be most frequent.

Inflammation may arise from injuries of various kinds, such as wounds, whether punctured, incised, lacerated, or contused; from the irritation of foreign bodies, such as renal, biliary, gouty, and salivary concretions; and from pressure, as in the instance of a bandage or ligature applied to the extremity; or in the example of pressure produced on an internal part by aneurismal or other kinds of tumours,

whether solid or fluid, the pressure of which causes inflammation in the parts to which it is applied.

Another exciting cause of inflammation is the direct application of heat. This is exemplified in the effect of exposure to the rays of the sun in producing inflammation of the brain or external integuments of the head and face, and in the effect of heat in producing scalds and burns.

The effects of cold, as an exciting cause of inflammation, more especially if combined with moisture, are well known. We observe inflammation occur in parts to which the external air has free access—the eye—the ear—the tonsils—the larynx or trachea, and the mucous membrane of the lungs, after exposure to cold. These are instances of the effects of the direct application of cold. At other times the application of cold is followed by inflammation of a distant organ, an indirect effect being sometimes thus produced on an internal part, by the local application of cold and moisture. Thus a person who gets the feet thoroughly wet may afterwards have inflammation of the throat, of the lungs, or intestines, according to some local but still unexplained predisposition. We have another exemplification of the effect of cold in producing inflammation in frost-bite, in which very often rapid destructive inflammation is set up from the application of intense cold.

Undue exercise of the functions of an organ may become not only a predisposing, but an exciting cause of inflammation. In this way undue exercise of the mental powers is a frequent cause of inflammation of the brain. In like manner, also, inflammation may be produced in the eye, as is frequently observed in persons who are obliged to use this organ unduly in their daily avocations. Inflammation of the vocal organs is a common consequence of long-continued loud speaking; hence noisy maniacs frequently become hoarse from the constant vociferation in which they indulge.

Some substances, when taken into the stomach as remedies in disease, produce inflammation of particular parts. We have an example of this in the inflammation of the salivary glands, and sometimes of the skin, produced by the exhibition of mercury, or in the gastro-intestinal inflammation which is the result of the employment of arsenic as a remedy in some diseases, but more especially when it is taken in such quantity as to act as a poison. To the same head of causes of inflammation, we may refer the various examples of local irritation and its consequences arising from irritant poisons. According to Dr. Christison, these effects of local irritation vary from the slightest redness to ulceration and even gangrene. Thus externally, alcohol reddens the skin; cantharides irritates the surface of the true skin, and causes vesication; tartar emetic causes deep-seated inflammation of the true skin and a pustular eruption; the juice of manchineel, spreading inflammation of the subcutaneous cellular tissue; arsenic has all of these effects, as also

death of the part and subsequent sloughing. Internally, alcohol reddens the stomach as it does the skin, but more permanently; while other substances, such as the diluted mineral acids, nitre, arsenic, cantharides, euphorbium, and the like, may cause all the phenomena of inflammation in the stomach and intestines, namely, extravasation of blood, effusion of lymph, ulcers, and gangrene.*

There are other substances belonging to the class of irritants—the acro-narcotic poisons—which have a compound action, the one local and irritating, the other remote, producing an impression on the nervous system. To this class belong the atropa belladonna (deadly nightshade), the datura stramonium (thorn-apple), and the nicotiana tabacum (tobacco).

The morbid animal poisons, as exciting causes of inflammation, belong also to this head. Some of these have a local action only, as the poison of itch or syphilis: more generally, however, the poison, though introduced locally, affects the general system, as in the instance of small-pox and cow-pox, and the poison of hydrophobia. It would appear, moreover, that some animal poisons operate through the medium of the blood. It is probably in this way that measles, scarlet fever, plague, the natural or uninoculated small-pox, and some other acute disorders, are produced. Many of these diseases, as is well known, give rise in their progress to various local inflammations, the danger to life depending in a great measure on the severity of these local lesions.

Terminations or effects of inflammation. The mode in which inflammation terminates depends on several circumstances, more especially the nature of the exciting cause, the intensity and duration of the symptoms, the peculiar constitution of the individual, the curative measures adopted, and the stage of the disease at which they have been employed.

1. *Resolution.* Inflammation may gradually subside by the unassisted efforts of the system, constituting spontaneous resolution; or its progress may be arrested by the employment of remedies before it has effected any change of structure in the part. Resolution is not only the most favourable, but the most common termination of inflammation: it is indicated by the progressive abatement of the local as well as general symptoms, and especially by the restoration of the natural functions of the part. When resolution takes place suddenly, the French writers apply the term *delitescence* (from the verb *delitescere*), implying sudden disappearance; this is exemplified when a primary inflammation suddenly disappears and attacks another organ. This sudden decline of the inflammatory action is less frequently observed, however, than the more slow and gradual process of resolution.

The resolution of inflammation is often preceded or accompanied by *metastasis*, or translation of the disease from one part to another. We have an instance of this in the common

* Christison on Poisons, second edit.

occurrence of inflammation suddenly leaving one tonsil and seizing on the other, in the sudden recession of the glandular inflammation in numps, and the subsequent inflammation of the testicle in the male, or the mamma in the female. In gouty and rheumatic inflammation, such sudden translation is frequently observed. The articular inflammation in gout sometimes recedes from the foot, and appears in the hand or knee, and occasionally attacks some internal organ, the stomach or brain. The sudden recession of rheumatism from joint to joint is a still more common occurrence, and is the cause of the generally protracted nature of this disease. A still more dangerous effect of the recession of rheumatic inflammation is, when it leaves the joints and fixes on the membranes of the brain or the serous covering of the heart.

Physicians, from observing the complete cessation of inflammation, when a secondary disease is produced, have endeavoured to imitate nature, and by means of derivation or counter-irritation applied in the vicinity of an inflamed organ, to establish an external disease, in the hope of withdrawing the inflammation from an internal to the external and less important part: these measures now form an important part of the local treatment of inflammation. (See COUNTER-IRRITATION AND DERIVATION.)

When inflammation is about to terminate in resolution, various changes take place according to the stage and intensity of the inflammatory action, and the structure of the inflamed part. In the slighter grades of the disease, the frequency of the circulation diminishes, the blood-vessels contract in their diameter, so that those, which during inflammation were so much dilated as to admit the red particles of the blood, again receive only a colourless fluid. When the inflammatory action has been more severe, the resolution is accompanied, if not effected, by an increase of the natural secretion of the part. If the inflammation occur in a serous membrane, the exhalents secrete an undue quantity of serum, or even coagulable lymph, which goes on so long as the inflammatory action continues; but whenever resolution takes place, the further progress of effusion is not only arrested, but the fluid already thrown out is gradually removed by absorption. When inflammation occurs in a mucous membrane, the natural secretion, though at first diminished, is afterwards increased, and more or less altered in its quality, more particularly if the inflammation have passed into the chronic stage.

Thus we find in bronchitis and muco-enteritis, that though in the primary stage of inflammation of these membranes the natural secretion is suppressed, as the diseased action proceeds, the natural secretion is first restored, and afterwards increased in quantity, and finally altered in quality. The error of attempting to check the secretion from an inflamed mucous membrane, especially in the early stage of the disease, the increased discharge being the natural solution of the diseased action, is, therefore, obvious. Besides these local circumstances which are observed

when inflammation terminates in resolution, we find occasionally other changes take place, which from their supposed influence in effecting this desirable solution, have been considered critical. There is sometimes an increase of the perspiration, or moderate diarrhoea, but more generally the urine exhibits marked alteration in its physical and chemical characters. While the inflammatory action is proceeding, the urine, though high-coloured, is clear, and does not, on cooling, deposit a sediment, but when the inflammation is disappearing, it deposits, on cooling, a red sediment. The following ingenious explanation of this appearance of the urine is given on the authority of Dr. Prout.

In healthy urine there is lithate of ammonia, which is pale and white, as also a yellow colouring matter, the nature of which is unknown, but which is thought to be, perhaps, a modification of lithic acid. If to lithate of ammonia out of the body what are called the *purpurates* be added, a pink substance is immediately produced, such as is observed in hectic fever; and if the urine have its usual yellow colouring matter, a mixture of that with the pink appearance produced by the purpurates and the lithate of ammonia gives a red colour, pink and yellow mixed together, forming a red colour. In this diseased state we are informed by chemists that nitric acid in excess is formed in the urine, which acts on the lithic acid, and converts some of it into a new acid called the *purpuric*, which, uniting with the salts of the urine, forms the purpurates; and these purpurates, mixing with the lithate of ammonia, which is always in the urine, produce a pink deposit, which, united with the yellow colouring matter, becomes red. The lithate of ammonia and soda are formed in some degree of excess in the urine under inflammation, and nitric acid is produced; which, as has been stated, acting on the lithic acid, produces purpuric acid; and thus the formation of the purpurates is explained. Those mixing with lithate of ammonia produce a pink substance; and when this unites with the yellow colouring matter, the colour is changed to red. The cause of the urine being high-coloured or red, without sediment, till the inflammation declines, is this, that the same substances are in the urine, but held in solution by the activity of the complaint; but when it declines, an excess of lithic acid is formed, producing *super-lithates*, which are very insoluble; and, therefore, a great portion of them falls down in the form of a precipitate; hence the red sediment.*

The resolution of inflammation is sometimes accompanied by hemorrhage, with which inflammatory action is often intimately connected. Critical hemorrhages may take place either immediately from the inflamed part or from some neighbouring organ. We have an instance of the one, in the hemorrhage which succeeds to inflammation of mucous membranes, and of the other, of epistaxis in apoplectic or inflammatory states of the brain.

* Elliotson's Lectures on Inflammation.

These spontaneous hemorrhages are always followed by most marked relief of the local and general symptoms.

When inflammation does not terminate in resolution, it effects other morbid changes in the inflamed tissue. The terminations, or, more properly speaking, the effects to which we allude, are *Effusion, Suppuration, Mortification, Ulceration, Induration, Softening, and Hemorrhage.*

2. *Effusion.* The exemplification of effusion as a consequence of inflammation is best illustrated in the serous membranes. After the violence of the inflammatory action has subsided, and the natural secretion of the membrane, which, during the primary stage of inflammation, had been suspended, is restored, an increased effusion of serosity takes place. The fluid which in these cases is secreted, and which happens only when the inflammation is moderate, bears so strong an analogy, both in its physical and chemical characters, to the serum of the blood, as to have received the appellation of serosity or serous fluid. It is generally of a pale straw-colour and transparent, though occasionally, when the inflammation is a little more intense, it contains a small proportion of albumen, which renders it slightly turbid. When the inflammatory action has been more violent, the fibrinous principle of the blood is separated; the admixture of which with albumen and serum constitutes coagulable lymph. It is this product which, when mixed with serous fluids, renders them turbid; the flakes of coagulable lymph, from their greater specific gravity, generally falling to the bottom of the cavity in which the effusion takes place, lining at the same time the surface of the inflamed membrane, and constituting that product termed *false membrane.*

When an intense inflammation has lasted several days, the fluid acquires a yellow colour from admixture of purulent matter: when this is considerable, the effusion very nearly resembles in appearance well formed pus; but it still contains a large proportion of coagulable lymph and serous fluid.

In the commencement of the formation of false membranes, the exudation is soft and without consistence; but from the thinner parts being gradually absorbed, they become more dense, and adhere to the inflamed membrane, forming webs of various figures, which extend from one point to another of the surface on which they arise. When subjected to pressure, they give out a large proportion of fluid consisting of serum mixed with albumen; the solid substance appearing globular when viewed with the microscope, and, according to the analysis of Davy, consisting chiefly of fibrine.

False membranes often become completely organised, and of a distinctly cellular structure, capable of being injected; and when the inflammatory action ceases, they are converted into cellular tissue covered with a serous membrane, and afterwards liable, like serous tissues, to inflammation.

Fibrine is also sometimes effused from in-

flamed mucous membranes, and gives rise to the formation of false membranes, such as that which is effused in the larynx and trachea, or from the mucous surface of the intestines or uterus. The false membranes formed in mucous cavities, however, are less consistent than those which are effused on serous surfaces, probably owing to their containing less of the fibrinous principle. When an inflamed mucous membrane is about to terminate in the exudation of a false membrane, an unusual quantity of viscid mucus is secreted, which gradually becomes more consistent from the admixture of fibrine which is effused in the subsequent stage of the inflammatory action. These pseudo-membranes, as was stated before, generally bear the mould of the cavities in which they form.

The organization of coagulable lymph gives rise also to the process of *adhesion*—an operation of nature by which surfaces of parts which have been recently divided become re-united, the lymph becoming a living intermedium whereby the continuity of the part is ultimately restored. A knowledge of the fact that parts which have been divided may be again united by adhesive inflammation, has laid the foundation of many of the most important improvements in surgery.

The mode in which divided parts are united, and injuries repaired, termed union by the first intention, is similar to that which takes place in the formation of false membranes. If a surface which has been divided, an incised wound for example, be examined a few hours after the solution of continuity has taken place, it will be found covered with a layer of coagulable lymph. Dr. Thomson made some experiments upon animals with the object of ascertaining the earliest period at which coagulable lymph is effused from the surface of a wound; he observed a distinct layer of lymph covering wounds he had made within less than four hours after they had been inflicted; though he thinks a longer period may be required in the human subject, in different persons, in different textures of the same individual, and in the different states of health and disease. The exudation of the lymph is speedily followed by the formation of bloodvessels, which often become, in the course of a few hours, so large as to be capable of being injected. This is the state of re-union termed by Mr. Hunter *adhesive inflammation.*

In many instances the reparation of an injury or divided surface is effected by a different process—that of *granulation*, termed by the older writers union by the second intention. The process of granulation takes place, when from various circumstances wounds do not unite by adhesive inflammation, or when there has been a considerable loss of substance in a part, as in abscesses, ulceration, and gangrene. In these cases a layer of coagulable lymph is effused on the surface of the wound, which, as in the process of adhesion, becomes penetrated with bloodvessels, and thus a living intermedium is formed. Soon afterwards the surface is covered with purulent matter thrown

out by a peculiar action of the vessels of the part, in which circumstance, besides the non-union of the divided tissue, the granulating differs from the adhesive process. Granulations assume the appearance of small red points and eminences, and according to Dr. Thomson, the mode in which nature effects their formation may be seen by injecting and carefully examining the internal surfaces of abscesses, or the granulating surfaces of healthy sores or ulcers. From numerous observations made in this way, it appears the exudation of a layer of coagulable lymph may be regarded as the first step in the process of granulation. The second consists in the penetration of this lymph with bloodvessels, nerves, and absorbents; the third, in the inosculation, or union by open extremities, of the vessels in these granulations; and in the last step, if it may be called so, of their formation, the granulations are covered over with cuticular substance by which the further secretion of pus is prevented, and the process of healing by granulation completed.* In this way the process of cicatrization is explained.

The subject of adhesive inflammation was minutely investigated by John Hunter, and in the chapter of his work on inflammation, entitled "On the Use of Adhesive Inflammation," he has pointed out this admirable contrivance of nature in preventing the extension of diseased action, and in repairing its effects in different structures. Mr. Hunter has also given a description, which has never been excelled in modern times, of the various processes by which this reparation is effected. The first step of the process by which solutions of continuity, whether simple incised wounds or loss of substance in any organ or part of the body are united or regenerated, is adhesive inflammation, which varies in intensity according as the reparation is to be accomplished by the first intention (adhesion), or by the process of suppuration. In the first mode, the inflammatory action never reaches the stage of suppuration; in the latter the inflammation should be moderate in order to insure cicatrization. It is well known to surgeons, that if a wound be irritated during the process of union by the first intention, the adhesive readily passes into the suppurative inflammation, so that the union by the first intention is frustrated; if, on the other hand, the surface of a suppurating wound be irritated during the healing by granulation, cicatrization is retarded and often entirely prevented.

The necessity, therefore, of moderating inflammation in the treatment of wounds, that this action, which is indispensable for the accomplishment of union by adhesion and cicatrization, may never exceed proper limits, or of occasionally stimulating the surface of a sore when the healing process is languid, is thus explained.

In every tissue adhesion is affected, as before explained, by the effusion and subsequent

organization of lymph, which in the course of time is transformed into a new substance, similar to cellular or fibro-cellular tissue, which adheres to the lips of an incised wound, and constitutes the medium or bond of union by the first intention; or it is deposited in the cavity of suppurating wounds, and upon which granulations are subsequently deposited, so as to fill up the vacuity which has been occasioned by the solution of continuity.

In the reparation of cellular tissue, the first stage is the effusion of lymph, which becomes gradually organized, and transformed into a texture so similar to the primary tissue, that it is impossible to distinguish the one from the other except by its greater degree of density or hardness, and that its cells do not communicate so freely, for in oedema the cicatrices of wounds or abscesses do not fill with fluid.

Serous membranes become united by adhesive inflammation, either by union of the two serous surfaces, as we observe in pleuritic adhesions, or when there is a solution of continuity of this membrane, as in wounds of the lungs or intestines. Dr. Thomson, states that in some experiments in which he removed a portion of the pleura pulmonalis, it appeared to be regenerated, as he was unable to distinguish easily the cicatrix from the surrounding parts. Gendrin also found the peritoneum thickened at one point in which ulceration of the intestine had commenced in the peritoneal tunic.

In solutions of continuity of the skin, when union by the first intention takes place, adhesion is effected by fibro-cellular tissue, which nearly resembles in formation the cutaneous structure. It differs, however, in some respects, chiefly in the non-regeneration of areolæ, indentations, or fatty matter. In extensive losses of the cutaneous tissue, the reparation is effected by suppuration, granulation, and the ulterior stage of cicatrization; but although the newly-formed substance is covered with an epidermis so as to resemble the original skin, it never acquires the perfect organization of cutaneous texture; it is less yielding, moveable, and elastic, and without indentations by which sound skin admits of distention. Its vitality is also less active, for, as is well known to surgeons, when an old sore breaks out, the cicatrix is gradually destroyed.

A similar process to that just described appears to take place when portions of mucous membrane are destroyed by ulceration, viz. the effusion and organization of lymph, and the formation of an organized cellular membrane. The newly-formed tissue, however, has none of the properties of a mucous membrane, and never performs the function of secretion. The cicatrix is generally white, contracted, and is neither endowed with villousities nor follicles. We have examples of the healing or cicatrization of mucous membrane in ulceration of the throat, bronchia, and urethra; and in the follicular ulceration which accompanies some forms of fever, and also in ulceration of the mucous membrane of the stomach, or of the colon in dysentery.

* Lectures on Inflammation.

The adhesive inflammation of bloodvessels is exemplified in wounds, or when a ligature is applied to an artery or vein. Effusion of lymph takes place both within the canal and on the surface of the vessel: this fluid becomes organized and finally transformed into a firm fibro-cellular web, which becomes closely connected with the internal and external tunics, and thus obliterates its canal. The fibrine of which the plug is composed is also organized, and may be even injected, shewing the distinction between this substance and a clot of blood.

A similar process takes place in inflammation of veins, which we have shewn to be more susceptible of adhesive inflammation than arteries; and that adhesive inflammation of this system of vessels frequently occurs, and gives rise to important and often dangerous diseases.

In nervous tissue, adhesive inflammation is observed in the reparation of various lesions of the brain and nerves, though pathologists are generally agreed that regeneration of the cerebral and nervous pulp never takes place. The process of adhesive inflammation of the cerebral tissue is exemplified in the obliteration of apoleptic or hemorrhagic cysts, in which, according to Rochoux, the appearance of the effused blood differs according to the duration of its effusion. When death ensues quickly, at the end of three or four days for example, it is in the form of soft blackish clots: after a month or six weeks it becomes firmer, assumes a deep brown colour, and resembles the blood of aneurismal tumours. At a more remote period it becomes still more compact, and of a pale red colour, bordering on ochreous matter; and lastly, it is entirely absorbed. Around the coagulum a layer of lymph is effused, which becomes organized and transformed into a cellulo-fibrous cyst, which separates the clot from the cerebral substance. When the coagulum becomes completely absorbed, the cyst gradually contracts, till its walls approximate, and finally adhere by thin bands of cellulo-fibrous tissue, which in some cases cross the cyst in various directions, so as to connect its opposite sides at these intersecting points. In many instances, however, the cyst remains open and is filled with a turbid fluid.

In wounds or laceration of nerves the divided extremities of the cord are united by lymph, which is gradually transformed into firm fibro-cellular tissue. From experiments which have been made with the view of ascertaining whether the true nervous pulp be regenerated, it is now generally admitted that such reproduction does not take place, the substance of the cicatrix not being capable of transmitting nervous impressions.

When muscular tissue is divided or destroyed, the reparation is not effected by the regeneration of muscular substance, but by very firm fibro-cellular tissue. This newly-formed substance becomes more firm according to the extent to which the extremities of the

muscle are separated. When this is considerable, the intervening substance becomes almost ligamentous, but never acquires either the appearance or properties of muscular fibre.

When solution of continuity or loss of substance of fibro-cartilaginous tissue (cartilage or ligament) takes place, the structure becomes swollen, inflamed, and softened; to which succeed effusion and organization of lymph, which is in process of time converted into dense fibro-cellular tissue; but it is in many respects dissimilar to the primary or original tissue.

The adhesive inflammation of bone is effected first by the effusion of lymph from the periosteal and medullary arteries, softening and swelling of the fractured extremities of the bone, the subsequent organization of their lymph, and its successive transformation, first into fibro-cellular tissue, then into a semi-cartilaginous substance, on the surface of which there are subsequently deposited a number of points of osseous substance. These points of ossification cohere, and form a thick irregular soft bony callus. The thinner parts of this callus are gradually absorbed, the solid bony substance alone remaining; and by the further absorption of the softer osseous particles, the medullary and cancellated structure of the bone becomes ultimately formed.

3. *Suppuration.* Inflammation may also terminate in suppuration or the formation of a fluid termed pus. Various opinions have been entertained as to the mode in which this fluid is produced.

The older writers ascribed it to the breaking down of the solids, and the changes subsequently induced in extravasated blood; some regarded it as the effect of putrefaction of the serum or of the chyle, while others imputed its formation to the wasting or melting down of the fat. In modern times the generally received opinion is, that pus is separated from the blood by a peculiar action of the bloodvessels of an inflamed part, analogous to that of secretion; but in what way this fluid is elaborated is as little understood as the mode by which the various secretions are formed from the parent streams. It would appear, from experiments made on this subject, that pus is formed by a gradual conversion of the coagulable lymph into this fluid. For a detailed account, however, of this process, the physical and chemical character of pus, as well as its mode of formation in different tissues and organs, we beg to refer to the articles ABSCESS and SUPPURATION, and to the section of this article, *Theory of Inflammation*.

4. *Mortification.* Mortification, or the complete death of a portion of the body, although produced by various causes, is not an unfrequent termination of inflammation, though it is a more frequent consequence of acute than of chronic inflammation. The terms gangrene, mortification, and sphacelus, have been used synonymously by many writers. Dr. Thomson has proposed to employ the term *gangrene* to express that stage of mortification which precedes the death of the part; and *sphacelus*, to

denote its complete death or mortification, the circulation and sensibility being completely destroyed.

When gangrene occurs as the effect of inflammation or other causes, or arises spontaneously, it is announced by a change of colour, sensibility, and temperature in the inflamed part. The bright red colour of inflammation is replaced by a deep purple, livid, or blue appearance, which soon passes into a dark brown or black; the affected part becomes insensible to the action of stimuli, while at the same time its temperature is diminished. It loses also the dense elastic feel which it had acquired during the inflammatory state, and becomes soft and flaccid; and if the mortification occur in the skin, the cuticle is raised in vesicles (phlyctenæ), which are filled with a yellow or bloody serum. A putrid odour begins soon after to be exhaled, which increases with the severity of the other symptoms, the progress of which is sometimes rapid, at other times more slow.

The complete death of the part is announced by a great decrease of temperature, a total loss of sensibility, and consequently cessation of pain, and a crepitous sensation produced by the presence of air as a consequence of putrefaction. It is also known to anatomists, that the structure of a sphacelated part is so completely changed that an injection cannot pass into the vessels.

When mortification occurs in external parts, recovery frequently takes place even under the most unpromising circumstances. In internal organs it is almost invariably a fatal lesion. The symptoms which denote mortification in parts of the body important to life are, sudden cessation of pain, remarkable depression of the powers of the system, with symptoms referable more to the typhoid than the inflammatory character; there is great restlessness and uneasiness, but not arising from pain; the countenance becomes anxious, the features shrunk, and the aspect wild and cadaverous; the pulse small, rapid, and irregular; hiccup followed by delirium and cold sweats, precedes the fatal issue.

We have already stated that mortification is more frequently induced by acute than by chronic inflammation. It is, however, important to bear in mind, that the death of parts is not always to be explained either by the degree or duration of inflammation. In certain epidemics, and in some conditions of the system, a state of local vascular excitement, amounting to little more than congestion, is followed by sphacelus of the affected parts. This is seen in the throat during the prevalence of malignant scarlatina, and in some forms of erysipelas: in malignant, eruptive, and typhoid fevers too, the inflammation produced in those parts of the body subjected to pressure or friction frequently terminates in gangrene.

There are few parts of the body which are not subject to gangrenous inflammation. Inflammation of the brain, though subject to all the changes consequent to inflammation,

rarely if ever terminates in gangrene, though its membranes have been found in a mortified state after external injuries. There are certain tissues, however, in which inflammation is more apt to terminate in gangrene than in others. Nature seems also to have endowed the vascular system with a remarkable power of resisting mortification. Surgeons have frequent opportunities of witnessing large bloodvessels exposed, and apparently in a sound state, when the surrounding structures are completely destroyed by gangrene or ulceration. It is well known that in gangrenous parts no hemorrhage follows the division of the sphacelated parts, or even an incision made several inches above the boundary between the dead and living parts. This is owing to the arteries being filled with a coagulum of blood, which adheres to the inner surface of the vessels so firmly as to resist the impulse of the blood when they are divided. In one instance, related by Mr. O'Hallason, no bleeding followed the removal of a limb, though the incisions were made four inches above the seat of gangrene: and Dr. Thomson saw, in a case of mortification of the thigh, a coagulum of blood in the external iliac artery, extending as high as the origin of this vessel from the aorta.

On the other hand, we observe that inflammation more readily passes into gangrene in some tissues and organs than in others. It is observed more frequently, as a consequence of inflammation, in the skin and cellular membrane, in the organs of digestion and respiration, than in other parts of the body. Mortification takes place also more rarely, and makes slow progress in muscular, ligamentous, and tendinous structures.

Besides the occurrence of mortification from inflammation and other external causes, it may arise, without previous inflammation, from the introduction of acrid poisons, from lightning, or the near approach of cannon-balls, or from animal poisons, such as that of the viper, cobra di capello, or the rattle-snake.

Mortification takes place not only as an effect of inflammation, and from the other circumstances just enumerated, but as an idiopathic disease. This form differs in some respects from that arising from the causes alluded to, and has been distinguished by the term *dry gangrene*, from the dry appearance of the mortified part, the skin, cellular tissue, muscles, tendons, and ligaments, being hard and dry, and shewing no tendency to putrefaction. It generally occurs in the lower extremities; and from the arterial trunks being almost invariably ossified, it has been supposed that this form of gangrene arises from this state of the bloodvessels.

It is a remarkable but well-ascertained fact, however, that dry gangrene may be also produced by eating unsound rye. The rye-plum or rye-corn (*secale cereale* of Linnæus) is used in some countries, particularly in the north of Europe, as an article of food, and also affords, by distillation, an ardent spirit. Bread made from rye is less nutritive but more ape-

rient than any other kind. This grain is liable to a morbid growth, more particularly when great heat succeeds to heavy rains. It is a black curved excrescence, not unlike the spur of a fowl, which grows on the spike, and is sometimes found in such quantities as to form nearly one-fourth of the produce of the rye. It is called *secale cornutum*, or the cockspur in rye. In France it is known by the name of the ergot (*siège ergoté*). This diseased growth is attributed to the destructive operations of an insect which perforates the rye-corn and destroys its parenchyma.

Unsound rye has a singular effect on the human body: viz. lassitude, weakness of the extremities, intoxication, and periodic convulsive movements. This state, which has been called *raphania*, or *convulsiones cerealæ*, continues from a few days to several months.

It is stated by Dodard and other writers, that persons who used rye-bread containing a considerable quantity of the diseased grain were liable to a gangrenous affection of the extremities, attended with little fever, inflammation, or pain, though the affected limb became dead, and separated from the body. The limb became at first cold and insensible, and in the progress of the disease dry, hard, and withered. For a full account of this curious subject, the reader is referred to Dr. Thomson's work on inflammation.

Mortification may, when it is slight, terminate, 1. by resolution; 2. by adhesion; 3. by ulceration; 4. by sphacelus, or the death of the part, the last being by far the most frequent termination. (See MORTIFICATION.)

5. *Ulceration*.—When a solution of continuity follows as an immediate consequence of inflammation, the morbid process by which it is effected is called *ulceration*.

Previous to the time of Hunter, ulceration was supposed to be produced by the corrosive power of the fluids of the part in which the diseased action occurred. This celebrated pathologist, however, demonstrated satisfactorily that the solution of continuity was not affected by the acrimonious quality of the fluids, but by the action of the absorbents, the removal of parts or tissues by these vessels constituting the ulcerative process. He designated the formation of an ulcer by simple loss of substance, *ulcerative absorption*; and when the solid parts covering abscesses, aneurisms, and deep-seated tumours, in their progress towards the surface, were gradually removed by ulceration, he applied the term *progressive absorption*.

Dr. Thomson has proposed to distinguish the separation of dead or mortified parts by the term *disjunctive absorption*; but this appears to be an unnecessary refinement of medical terminology. Ulceration may occur as a consequence of every degree or kind of inflammation, not only in soft parts, such as skin, mucous membrane, brain, lung, liver, &c., but also in the texture of bone, in which structure the ulcerative process is termed *caries*. Indeed, we find that all textures of the body are susceptible of ulceration. "We see this exem-

plified," Mr. Lawrence observes, "when mortification has attacked an entire limb, and when the separation takes place by a natural process. Suppose, for instance, that the foot and lower part of the leg were mortified, and that the mortification stop in the middle of the leg, we find that the skin, the cellular membrane, the fascia, the muscles and tendons, blood-vessels, nerves, and even the bone itself, are all penetrated by the process of ulceration."^{*}

Another familiar illustration of the progress of ulceration is observed in the progressive absorption which takes place in an internal aneurismal tumour, in which we find the sac of the aneurism adhering to the parts with which it comes in contact, but after forming an intimate bond of union, the mass is gradually though slowly removed by the process of absorption; even the bone which intervenes between the external surface and the aneurism being finally absorbed.

It is this removal, Dr. Thomson remarks, of one texture after another, first the sac of the aneurism, then the *pleura costalis*, then muscles, bones, cellular substance, and cutis, layer after layer, that Mr. Hunter wishes to express by the term *progressive absorption*—a term sufficiently expressive of the general phenomena which it exhibits, and of the gradual and successive disappearance of the parts which cover abscesses, aneurisms, and tumours, in their constant and uniform progress to the skin. In this process the adhesive inflammation precedes the outward progress of the aneurism, and limits, as in phlegmon, the extent of the swelling, and, as it were, directs it to the surface of the body.[†]

The occurrence of ulceration is much more frequent in some textures than in others, depending on the degree of vascularity of the part which it affects. It is observed also to be a more frequent effect of chronic than of acute inflammation. The skin appears, of all other tissues, to be most susceptible of ulceration. Mucous membranes, cellular tissue, bones, and articular cartilages, come next in order. Fascia, ligamentous structure, and tendons, are the least liable to ulceration. Hence, as Dr. Thomson states, when abscesses form under ligamentous or fibrous fascia, we find that they are long in getting to the surface, and that they seldom arrive at this by the shortest and most direct road, but usually by passing through some texture or organ that is more susceptible of being absorbed.

It is important to remark, however, that inflammation of the same tissue, apparently the same in kind, degree, and duration, will terminate at one time in ulceration, and at another pass off without producing solution of continuity. The importance, therefore, of ascertaining those circumstances which influence the termination of inflammation in ulceration must be obvious.

The mode in which ulceration proceeds in the different tissues and organs, the effects to which it gives rise, and many other points con-

* Lectures on Inflammation.

† Ibid.

nected with this important pathological state, will be discussed in detail under the article **ULCERATION**.

6. *Induration*. This effect of inflammation is frequently observed. When it follows acute inflammation, it depends on the presence of fluids effused into the tissue of the inflamed part; when it takes place as an effect of chronic inflammation, it is more frequently produced by the presence of various solid products to which this process gives rise. Induration is most generally observed in soft spongy cellular organs, as the brain, cellular membrane, lungs, &c., but more frequently in the two latter tissues, in which the induration subsequent to inflammation is often very considerable, and produces remarkable alteration in their structure.

7. *Softening*. An opposite state, that of softening, is not an uncommon effect of acute inflammation. Although it is observed to take place in all tissues, it most frequently occurs in the substance of the brain, mucous membranes, and cellular tissue. As this subject is one of great practical importance, and has of late been very fully investigated, it will be fully considered under the article **SOFTENING**.

8. *Hemorrhage*. Inflammation is often followed by hemorrhage. The effusion of blood may take place from almost every tissue and organ in the body, but more frequently from those parts which are covered with mucous membranes. The various circumstances under which hemorrhagic effusions, as a consequence of inflammation, take place, will be found under the article **HEMORRHAGE**.

Treatment. From the serious and often fatal effects of inflammation, it is of the greatest importance to endeavour to subdue the symptoms on their first appearance, that those terminations or effects we have been considering, some of which have a dangerous and often fatal tendency, may be prevented. The necessity for the adoption of prompt measures is more especially necessary when the inflammation is seated in an organ essential to life, in which the changes of structure frequently go on with great rapidity, so as either permanently to injure the function of the part, or to destroy life. Thus, when inflammation attacks the brain, lungs, heart, or intestines, or when it occurs in parts the organization of which is so delicate that the inflammatory action speedily destroys the structure and functions, as, for example, the retina or iris, the ear, or the larynx, the most energetic treatment should be adopted on its very first appearance. Another reason for the immediate employment of suitable measures in inflammation even in parts which are less essential to life, is, that when the blood-vessels become unduly distended for any length of time; they contract with difficulty, and thus give a greater susceptibility to recurrence of the inflammatory action, or, in other words, a predisposition to relapse.

Before commencing the treatment of inflammation, if any obvious exciting cause exist, it is proper to endeavour to remove it, and also to avoid every circumstance which can tend to keep up local or general excitement.

The object to be kept in view in the treatment of inflammation is to effect resolution. This is, in some instances, the natural and spontaneous solution of the disease, though in the majority of instances it is induced by measures which tend to subdue the local and constitutional excitement. It is necessary, in estimating the probability of accomplishing such a desirable termination, to consider the duration of the inflammation, since we can only hope to bring about resolution in the more early stages. Even although the measures employed prove inadequate to this end from the duration of the symptoms before their application, still the severity or extent of the termination which may have ensued may be materially lessened by the judicious employment of means calculated to subdue inflammatory action.

The remedies by which the symptoms of inflammation are removed have been termed antiphlogistic treatment, that is, remedies against inflammation. We have seen that the capillaries or vessels, which in the natural state admit only the colourless part of the blood, become so enlarged during inflammation as to admit red blood, and from their being thus surcharged, are inadequate to carry on the circulation. We have also seen that with this local congestion the vascular system throughout the body sympathizes, giving rise to symptomatic fever, during which the blood, being impelled with unnatural force, increases the distention and obstruction in the capillary circulation. These circumstances at once shew the necessity of bloodletting as the principal means of removing inflammatory diseases.

In all cases of active inflammation, but more especially when the constitutional symptoms are severe, general bleeding is to be employed, with the object of diminishing the quantity of blood, and, at the same time, of abating the force and frequency of the action of the heart and arteries. The abstraction of blood from the system is more especially necessary in inflammation of important organs, as of the brain, pulmonary and abdominal viscera, in which diseases it forms the principal means of cure.

It is generally found that inflammation of serous membranes requires larger losses of blood than when the parenchyma or substance of an organ is inflamed, and that, on the other hand, inflammation of mucous surfaces is less under the controul of general bleeding; in such cases the local is preferable to the general abstraction of blood.

The propriety or necessity for general bloodletting being determined, the question as to quantity requires consideration. For this there cannot obviously be any fixed or determinate rule, as it must depend on the importance of the organ inflamed, the intensity of the inflammation, its duration, and the peculiar circumstances which each case presents. When an organ important to life is inflamed, and if there be no special circumstances to forbid copious bloodletting, the effect produced on the symptoms is a matter of greater moment than the quantity of blood abstracted.

The too common practice of prescribing a certain number of ounces of blood to be drawn from a vein in an acute disorder is most reprehensible. The disease may yield to the abstraction of a few ounces of blood, or a much larger quantity than was at first anticipated may be necessary. Hence the obvious advantage of the physician superintending the bloodletting he prescribes, in all cases of emergency. Every practitioner must have seen cases in which, though he had imagined a moderate bleeding (sixteen to twenty ounces) would have cut short the disease, a very considerable quantity of blood has been lost before an impression was made on the symptoms. In one case of pericarditis which lately fell under our observation, in which, after the disease had been nearly subdued, a recurrence of the symptoms took place with redoubled violence, according to usual custom twenty ounces of blood were ordered to be drawn from the arm. From the urgency of the symptoms, however, we superintended the operation. No relief of the pain was obtained after twenty, thirty, forty, and fifty ounces were abstracted. When sixty had been taken away, the patient exclaimed, "I now feel relieved." This large bleeding was necessary as a means of relief from most acute suffering. Besides the quantity abstracted, the rapidity with which the blood flows has an important influence on the symptoms. The blood should be drawn from a large orifice, that a decided impression may be at once made on the disease; for which purpose, in cases of inflammation of a vital organ, a vein in both arms may be opened, and the blood allowed to flow till there is an approach to syncope, which may be favoured by placing the patient in the erect posture, whereby the flow of blood to the heart and upper parts of the body is retarded. It is incredible the quantity of blood which some patients have lost before inflammation of an internal organ has been subdued. The late Dr. Gregory used to relate in his lectures the case of a young woman who lost two hundred and thirty ounces of blood in the space of a few days, before an attack of pleurisy was overcome. Such large bleedings, however, are seldom necessary.

The effect of bloodletting, more especially if carried to approaching syncope, in lessening inflammation, may be observed by comparing the state of the conjunctiva in acute ophthalmia, before and after the patient has been freely bled. The distended and tortuous vessels are no longer visible, and for some time after the conjunctiva often remains as pale as in its natural state. The same effect is produced on internal organs, and those structures which are not visible.

It is seldom that a single bleeding is sufficient to subdue active inflammation, even when carried to a sufficient extent. The disease may for a time appear subdued, but when the system rallies, when reaction succeeds to the depression consequent on a profuse bleeding, the symptoms re-appear sometimes with the same intensity as at first, but more generally

in a mitigated form, and require a repetition of the bleeding. We have sometimes seen the abstraction of a few ounces of blood, when the pulse was beginning to rise, indicating the period of reaction, give a final blow to the disease. Hence, in active inflammation, we are disposed to recommend, an hour or two after the first bleeding, the bandage to be re-applied, and a small quantity of blood (eight to ten ounces) to flow from the orifice. Even with this precaution the symptoms in many cases return, and therefore it is necessary to consider those circumstances which indicate the necessity of the further abstraction of blood, and the extent to which it should be carried.

1. There are some particular symptoms from which an indication as to the further loss of blood may be taken. We have observed that the effect of inflammation in an organ is to disturb seriously its functions; hence, when the natural function of an inflamed organ is restored, it is a true criterion of the cessation of the inflammation. When, however, the function of the part is only partially restored, or if, after being completely recovered, it again become disturbed, it is a sure proof that the inflammatory action is still lurking, and may, on the application of a trivial exciting cause, be again called into its former activity. Under such circumstances the further abstraction of blood will be necessary.

2. Another symptom requiring consideration as to the propriety of repeated bloodletting, is pain. In the early stage of inflammation it is more or less acute, but generally mitigated or removed by venesection; and when a moderate bleeding produces partial or complete cessation of pain, it proves that the inflammation has not made great progress. In other cases the relief from pain is less instantaneous or considerable, but takes place gradually with corresponding abatement of the other symptoms, and is often completely removed by local bleeding and counter-irritation. If, however, the pain be only partially mitigated, or its removal be of short duration, or after having been completely removed, it recur, announcing the renewal of inflammation, there can be no hesitation about the necessity of further depletion.

Again, we find that when acute passes into chronic inflammation, the pain abates, and ultimately entirely ceases, which may lead to the impression that the inflammation has been extinguished. Acute pain not unfrequently supervenes in such cases, and announces the conversion of chronic into acute inflammation, requiring a repetition of bloodletting and other measures for its reduction.

It is necessary, however, to remark that young practitioners are too often deceived in the expectation of acute pain in inflammatory diseases. We have already seen that when inflammation is allowed to proceed and to assume the chronic form, the pain abates, and at length finally ceases.

In many of the phlegmasiæ there is no pain, even when intense inflammation is going on. This is more especially the case in inflamma-

tion of the parenchyma of organs; in the brain, for example, in which most active disease may be proceeding even to a fatal termination without any indication of pain. If, however, the symptoms be analyzed, abundant proofs will be given of the existence of serious inflammatory disease. Again, in pneumonia or inflammation of the pulmonary tissue, there is often no pain, the disease being indicated by cough or embarrassed respiration, and the crepitating sound of the breathing; or in cases of latent pneumonia, by the stethoscopic phenomena alone. Even in the advanced or chronic stage of inflammation of serous membranes, the pain abates or entirely subsides, while slow and insidious inflammation is going on. Were the practitioner to overlook such symptoms, and to imagine that in the absence of local pain inflammation did not exist, the life of his patient might be sacrificed.

3. The pulse has from the remotest antiquity furnished an indication of the propriety of bloodletting, and of the necessity for its repetition in acute diseases. In the phlegmasiæ the pulse is increased in frequency, and in volume or strength; and in inflammation of serous membranes it acquires more or less hardness, wiriness, or tension. The object of bloodletting is to reduce these states of the pulse, more especially the hardness, and in proportion as this is accomplished, the operation is beneficial; so that when we fail in removing this hardness of the pulse by profuse bleedings, the issue of the case is seldom doubtful. It is necessary, however, to bear in mind, that in cases in which large losses of blood have been sustained, the reaction is often accompanied with a hemorrhagic throb or jerking of the pulse. We have often seen bloodletting prescribed for this state of the pulse, and observed that it invariably increased by the depletion, the crassamentum of the blood, at the same time, becoming progressively smaller at each bleeding. In these cases there is exhaustion with excessive reaction—a condition of the circulation which tends to impel the blood in inflamed parts, so that bloodletting proves indirectly a stimulating rather than an antiphlogistic measure when employed under such circumstances.

The state of the pulse alone, however, without reference to the general symptoms, is not always a safe criterion of the necessity for bloodletting. We find in many inflammatory diseases that the pulse does not exceed the average frequency or strength observed in health, so that were the practitioner to withhold his lancet solely because the pulse deviated little if at all from its natural state, a serious or often fatal error would be committed. In such cases the degree of pain or other local symptoms of inflammation must regulate the practice. We very lately found it necessary to abstract once and again a considerable quantity of blood from a patient with abdominal inflammation, whose pulse did not reach the ordinary average frequency. In this case it was discovered afterwards that the ordinary quickness of pulse did not exceed sixty. Again, in the early

stages of inflammation of the brain, the pulse seldom exceeds the natural standard, or is often even slower than usual, though it is generally observed to rise after bloodletting. The state of the local symptoms, therefore, is always a more safe criterion of the propriety of adopting active measures in inflammatory diseases than either the pulse or the general symptoms.

4. The appearance of the blood, when drawn, will frequently, in conjunction with other symptoms, afford assistance as to the propriety of further abstraction. We do not think that the buffy coat, which has been regarded as a test of the presence of inflammation, should much influence the decision, as we find it occasionally wanting in inflammatory diseases. When, however, the blood on cooling exhibits the buffy coat, more especially when it is tenacious, the crassamentum firm, the pulse wiry or corded, and the pain unsubdued, it may be confidently predicted that the inflammation is not subdued, and therefore more blood may be safely and advantageously taken. In the advanced stages of inflammation in persons whose powers are feeble, or when blood has been repeatedly abstracted, though the blood still exhibits the buffy coat, it is soft, and the coagulum loose. It appears, indeed, from the experiments of Prevost and Dumas, that when blood has been repeatedly abstracted, the red particles are diminished in number; and were we to judge from the gradual diminution of the fibrine, it would seem that this principle is also lessened. This appearance of the blood shews that inflammation still exists, but that no advantage will be derived from further bloodletting.

5. A most important circumstance, which it is necessary to consider in the treatment of inflammation by bloodletting, is the period or duration of the disease. If the symptoms have been allowed to go on without any effort being made to subdue them, it is vain to expect the same results from the vigorous use of the lancet, as in the more early stage. Profuse bleeding has less influence on the local disease than on the general powers; so that when inflammatory disease has slowly but steadily increased in an enfeebled habit, while at the same time the insidious approach of the symptoms has been overlooked, the patient has a better chance from the judicious employment of modified antiphlogistic measures, of which a moderate bleeding may often form part.

6. It is almost unnecessary to state that the quantity of blood extracted in inflammation must, with other circumstances, have reference to the age of the individual. The diseases of infancy are generally of the inflammatory kind; but it is very difficult to open a vein in infants. In such cases one or two leeches may be applied to the back of the hand or foot, and the bleeding afterwards encouraged by warm fomentations, or immersing the limb in tepid water. In the older infant, the number of leeches must be increased according to age. In some instances the leeches may be applied to the neighbourhood of the inflamed organ;

as by this mode of abstracting blood the local symptoms are not only more speedily arrested, but the general symptoms, with which every form of acute infantile disorder is almost invariably accompanied, are reduced.

In childhood greater advantage is often derived from venesection than in infancy; indeed the active forms of disease at this period of life are too often overlooked, the practitioner being satisfied with the local detraction of blood, while the bolder measure of venesection is required. It is true that blood is less easily drawn from the veins of the arm in children, but there is ample resource in the jugular, from which any quantity may be taken by a little adroitness on the part of the surgeon.

The period of life when bloodletting is most required, and produces the most decided effects, is from manhood to middle age, when the powers are vigorous. After the middle age the powers decline, and the system is less able to contend with active disease, and the remedies necessary for its removal. While at the one period bloodletting may be carried fearlessly to the required extent, the practitioner must be more cautious when he is contending with acute disease at an advanced age.

7. Physicians often derive useful information from observing the prevailing type of diseases. In idiopathic fevers more especially, this knowledge is almost indispensable for the safe conduct of the case. The same observation is applicable to the treatment of inflammation, in which there is often a material difference in the intensity or activity of local and constitutional symptoms, as well as of the power of the system to bear large losses of blood. The most palpable illustration of this is the different types of fever which accompany puerperal or child-bed fever, which is well known to require different treatment according to the prevailing character of the epidemic.

7. Much has been said about the influence of temperament in determining the treatment of inflammatory diseases. The diseases of the sanguine temperament have been supposed to be of a more acute character, and to require a more active mode of treatment, than the melancholic or nervous. Greater weight, we apprehend, has been given to this notion than experience has warranted. Were the acute disorders of those of the melancholic temperament to be treated on this idea, serious errors would undoubtedly be often committed. The fact seems to be that persons of the sanguine temperament are more predisposed in general to acute or inflammatory diseases, and consequently are more frequently the subjects of them than those of the melancholic, bilious, or nervous; but when inflammation has once taken place, there is less difference as to its intensity, from the constitution or temperament of the individual, than has been usually imagined.

We have been considering hitherto those cases of inflammation in the treatment of which general bloodletting is required. It is not, however, always necessary to take blood from the system, the topical abstraction being

often sufficient to accomplish the cure. Cases also frequently occur in which the loss of even a small quantity of blood from the system is followed by considerable inconvenience and exhaustion, though the same amount of blood abstracted locally is followed by excellent effects.

This mode of bloodletting may, therefore, be employed—1. when the amount of inflammation is trivial; 2. when the powers of the patient are too weak to admit of general bloodletting; 3. when the active stage of inflammation has been allowed to pass over, and is therefore little under the controul of general bloodletting; 4. as an auxiliary to general bloodletting, when further loss of blood from the system is deemed unnecessary. Moreover the local abstraction of blood may be often so managed as to secure the advantage of a general bleeding. Thus, when blood is taken from the temporal artery or from the jugular vein in diseases of the brain, the quantity may be so regulated as to obtain this double advantage: hence the preference given to this mode of bloodletting in acute diseases of the brain.

With regard to the mode of abstracting blood locally, cupping is preferable to leeching in all cases in which it can be employed.

The blood is more rapidly abstracted, and the quantity more nicely regulated. There are regions of the body, however, to which cupping-glasses cannot be applied; under such circumstances recourse must be had to leeches in suitable numbers.

Another powerful antiphlogistic measure in the treatment of inflammation is the exhibition of purgative medicines, which not only remove accumulated secretions, but, according to the class of purgatives employed, produce, by their action on the intestinal exhalents, a powerful derivation from the circulating system. Hence great advantage is derived from a combination of cathartics, which may be administered in suitable doses and at longer or shorter intervals, according to the indication to be fulfilled.

By active purging the general powers may be very much lowered; so much so, indeed, that mild cases of inflammation often yield to the exhibition of purgatives alone, though the more sure and efficacious practice is to employ at the same time other antiphlogistic measures, more especially bloodletting, general or local, according to circumstances.

There is another principle on which the beneficial operation of cathartics may be explained, viz. that of revulsion. When a powerful medicine of this class is exhibited, a copious secretion from the surface of the alimentary canal takes place: the sudden removal of so much fluid from every part of the system not only lessens the quantity of liquids in the diseased as well as the healthy parts of the body, but in the general determination to the bowels, the irritation has been supposed to be diverted from the local inflammation to the intestines. We apprehend, however, that the benefit derived from free purging in inflammation is

more owing to the abstraction of fluid, than to the revulsion which may be induced.

The employment of purgatives is more applicable to some forms of inflammation than to others. The circulation in the brain is readily affected by purgatives, as is evident from the paleness of the countenance, and the syncope induced by active cathartics. Hence in all cases of cerebral congestion and inflammation, purging ought never (unless under special circumstances) to be omitted. In threatenings of relapse, the exhibition of purgatives often supersedes the necessity for local or general bloodletting; and from the intimate sympathy which exists between the intestines and brain, the necessity of attending to the proper regulation of the bowels in the stage of convalescence from acute diseases of this organ must be apparent.

In thoracic inflammation purgatives form part of the antiphlogistic treatment. Experience, however, shews us that they are less efficacious in this than in some other forms of inflammatory disease; and, therefore, when there is evidence of pulmonary inflammation, more reliance is to be placed on the general and topical abstraction of blood than on the exhibition of purgatives; and when there is gastro-intestinal complication, they are to be rigidly withheld.

Since the morbid states of the alimentary canal have been so thoroughly investigated, practitioners are more guarded in the exhibition of purgatives in the treatment of abdominal inflammation. It is necessary to sweep out the bowels once or twice by some active aperient in the commencement, except when the mucous membrane is the seat of inflammation. It is a great source of anxiety with many practitioners to procure the free action of the bowels in peritonitis, which led the late Dr. Saunders to remark, in his lectures on peritonitis, that the best mode of opening the bowels is by the lancet; a practical precept in which we perfectly agree, as there can be no question of the mischievous effects arising from irritating the bowels by cathartics at a time when it is most important that every source of disturbance be averted.

When the peritoneal inflammation is subdued, the bowels are readily opened by comparatively mild aperients: indeed, this soluble state of the bowels is a tolerably sure criterion of the subsidence of the peritonitis. Much harm is also often done by injudiciously irritating the bowels after the inflammatory symptoms have disappeared; and we have many times traced the recurrence of enteritis to the constant irritation of the bowels by purgatives administered with the object of simply effecting their evacuation, which may be at all times ensured by emollient glysters, or a small quantity of castor-oil.

If it be necessary to be cautious in the employment of purgatives in peritonitis, it is more particularly so in inflammation of the mucous membrane of the intestines, which is not only a very common primary disease, especially in children, but a frequent complication of other acute disorders. It is unnecessary,

however, to do more than to allude to this subject in this place, as it has been already fully and ably discussed. (See ENTERITIS and GASTRO-ENTERITIS.)

Mercury is a remedy of considerable power in arresting inflammation, either in conjunction with bloodletting, or in cases in which the loss of blood is deemed inexpedient. The beneficial effects of this medicine is best exemplified in the treatment of intis, in which disease its power of controlling inflammation and in preventing the effusion of lymph, or, when effused, of effecting its absorption, are quite perceptible. Another illustration of the powers of mercury in checking the progress of inflammation is observed in inflammation of the larynx and trachea, in which organs, from their delicacy of structure, serious consequences often arise when the inflammation is not speedily arrested.

There can be little question that it exerts a similar influence over inflammation of internal parts, and appears to have a peculiar power in arresting or controlling the action of the capillaries, and of preventing those changes from taking place which are so destructive to the organization of inflamed tissues. In other instances, when the inflammation has assumed a chronic form, and consequently is little if at all under the influence of any form of bloodletting, mercury may be employed with the most decided advantage. The quantity in which it is administered must depend on the violence of the inflammation and the organ that is affected. It is in some cases necessary to bring the system more rapidly under its influence than in others; for instance, in inflammation of the iris, the larynx, or of the trachea. Therefore, after general or local bleeding, two grains of calomel, or five of the hydrargyrum cum creta may be given every alternate hour till there be some decided amendment in the symptoms. In diseases of less urgency, the same quantity may be given at more distant intervals, every four, six, or eight hours, according to circumstances. When the mercury produces purging, it must be combined with opium; or, if opium be improper, some of the ordinary astringents—catechu, kino, or chalk may be employed. Some physicians recommend much larger doses of mercury—ten, fifteen, or even twenty grains of calomel at once, and do not hesitate to repeat these enormous doses at short intervals. We confess we have never seen any case of inflammation which, if curable at all, resisted the more moderate doses we have advised. In the inflammatory diseases of hot climates, which run their course with frightful speed, the rapid introduction of mercury after venesection seems to be the only chance of saving life. In the acute diseases of temperate climates, however, most practitioners prefer the smaller doses, repeated at longer or shorter intervals according to circumstances.

Though mercury is capable of arresting the progress of inflammation when exhibited alone, it is often more successful when combined with opium. This is more especially necessary when there is much suffering from pain.

As a general principle opium is inadmissible in inflammation, until the excitement has been reduced. That it is a stimulant has been proved by most carefully conducted experiments on the lower animals, as well as by observation of its effects on the human body both in health and disease.

We have just adverted to the exhibition of calomel and opium in the treatment of inflammation. The notice of the profession was, many years ago (1783), first directed to the efficacy of this combination in the treatment of inflammatory diseases by Dr. Robert Hamilton, of Lyme Regis. He acknowledged that the practice was first suggested from the favourable accounts he had received from a navy surgeon of the treatment of hepatitis by mercury. He adopted the hint, and found the practice successful in the hepatic inflammation which frequently accompanies the bilious, intermittent, and remittent fevers of this country. He soon, however, found it necessary to add opium to relieve pain, which happily most effectually answered that purpose. The success of this mode of treating hepatitis induced Dr. Hamilton to conclude, that it would prove equally so in every form of internal inflammation. He first prescribed calomel and opium in peripneumony, and was successful in a large proportion of cases, and under a variety of circumstances. The cases of pleuritis, enteritis, and child-bed fever, in which it was employed, also speedily vanished.

The efficacy of this combination in arresting internal inflammation led to its employment in acute rheumatism and in gout; and Dr. Hamilton had the satisfaction of seeing these diseases also give way most readily under its use. The following is a summary of Dr. Hamilton's mode of prescribing it. After bleeding and evacuating the bowels, a pill containing from five to one grain of calomel, and from one to a quarter of a grain of opium, according to the age and powers of the patient, was directed to be administered every six, eight, or twelve hours, according as the intensity of the inflammation and aspect of the disease required,—plentiful dilution with barley-water or any weak tepid beverage being at the same time enjoined. When there was much fever, with dry parched skin, tartar emetic and sometimes camphor were added; this combination had the effect of determining powerfully to the skin, and promoting the action of the kidneys and bowels. After three or four pills taken in the course of twenty-four hours, the symptoms were evidently relieved; in other twenty-four, the disease gave way and soon terminated. If, however, there was no abatement of the inflammatory symptoms in the first twenty-four hours, more blood was abstracted, the calomel and opium given more frequently, and continued till the force of the disease was subdued.

It was remarked that when the mercury induced much sweating and purging, the salivary glands did not become soon affected; but it was not uncommon to observe the patient greatly relieved, though the mercury did not affect the mouth, or produce any visible evacuation,

except a slight increase of urine or insensible perspiration.

The mercurial plan was almost invariably successful when employed early in the disease; but when adopted in the later stages, its efficacy was more uncertain, though when the mercurial action could be induced on the salivary organs, the recovery was more sure. Counter-irritation was at the same time adopted when necessary.

With regard to the allegation that, as the calomel had been combined with other powerful medicines, the beneficial effects might with greater probability be ascribed to them than to the mercury, Dr. Hamilton states, that though he always regarded the opium as of the most essential service in relieving pain, and that the tartar emetic and camphor have sometimes contributed to the cure, he had often seen cases in which tartar emetic, camphor, and opium had been for some days employed without affording the smallest relief; but on the addition of calomel, the symptoms gave way in a very short time; the amendment seemed in many cases, indeed, to take place as the salivary glands became affected.* Subsequent experience has amply confirmed the practical deductions of Dr. Hamilton as to the efficacy of calomel and opium in the treatment of inflammatory diseases. This combination forms an admirable auxiliary to the use of the lancet in internal inflammation; and when the period for bloodletting has passed over, gives the patient the best chance of recovery.

Neither this nor any other remedy, however, must be permitted to interfere with bloodletting in active inflammation. Mercury may assist in controlling inflammation and render less bleeding necessary, but is in itself inadequate to subdue it. It is, in the first place, necessary to break the force of the disease by venesection, and afterwards to exhibit mercury, care being taken not to push this remedy too far, as it has been observed that its specific effects take place very readily when large quantities of blood have been abstracted.

When the inflammation has passed into the chronic stage, which precedes alteration of structure, mercury is the best, often the only mode of removing it.

Many physicians consider that in active inflammation the administration of opium alone, after a full bleeding, is followed by the most happy effects, especially in irritable habits. We have often in our practice, as well as in that of others, witnessed its efficacy. After bleeding the patient to approaching syncope, having regard to the effect rather than to the quantity abstracted, the reaction which generally follows a large bleeding may often be prevented by two grains of solid opium, or a draught containing one grain of pure acetate or muriate of morphia, administered when the faintness is disappearing. The heart's action is thus controlled, while the nervous system is tranquilized; so that the patient enjoys an interval of refreshing sleep, from which he often awakes with a soft skin and freedom

* Duncan's Medical Commentaries, vol. ix.

from pain. In many cases this practice, with a moderate cathartic, is sufficient to arrest the inflammatory disease. If, however, after an interval of three or four hours, the symptoms return, with hot skin and wiry pulse, the blood-letting must be repeated, and two grains of opium with three or four of calomel given as before. It may in these instances be advisable to administer afterwards a few doses of this combination in smaller quantities—two grains of calomel with half a grain of opium at intervals of three or four hours.

This practice has been strongly recommended by the late Dr. Armstrong, who emphatically said of Dr. Hamilton's treatment, that "it deserves to be written in letters of gold, on account of its great practical utility." In a paper written by this physician in the *Transactions of the Associated Apothecaries*, entitled "On the Utility of Opium in certain Inflammatory Disorders," he recommends the more early and free use of opium, evidently considering that the great advantage arises from the administration of the opium alone. He advises, after bleeding to approaching syncope, three grains at least of good opium, to be given in the form of a soft pill; and that strict quietude be enjoined, in order if possible to procure sleep. In some instances Dr. Armstrong found a smaller quantity of solid opium sufficient; but the dose was made equal by a portion of laudanum, which in highly irritable habits is preferable, because the sedative influence of the opium is thus more speedily procured. On some occasions, where a great quantity of blood has been lost in irritable persons, a large dose has been given after venesection, never however beyond five grains of solid opium, nor a drachm of the tincture at once.

The effects of opium thus administered, according to Dr. Armstrong, are to prevent a subsequent increase in the force or frequency of the heart's action, and a recurrence of pain, while it induces a tendency to quiet sleep and copious general perspiration.

Dr. Stokes has recently brought this subject before the profession in an excellent practical paper* in the first volume of the *Dublin Medical Journal*, written chiefly with the view of pointing out the advantage to be derived from the administration of opium in peritonitis, occurring under circumstances where bloodletting cannot be employed. The cases alluded to are—1. peritonitis arising from the escape of fecal matters into the peritoneal cavity, through a perforating ulcer of the intestine; 2. peritonitis arising from the bursting of an abscess into the serous cavity, or from rupture of the intestine induced by external violence; 3. peritonitis occurring after the operation of paracentesis in delicate subjects; 4. low typhoid peritonitis occurring after delivery.

In these cases of peritonitis, the rapid sinking of the vital powers renders bloodletting and

the usual treatment in common peritonitis inadmissible; the indications are to support the strength of the patient as far as circumstances permit, and afterwards to endeavour to prevent the further effusion in the peritoneal cavity, by inducing organization and adhesions of the effused lymph. For this latter purpose, Dr. Stokes thinks, opium in large doses pre-eminently calculated. This practice was first suggested from the successful treatment, by liberal doses of opium, of two cases of peritonitis after tapping, and of another from the effusion of purulent matter into the cavity of the belly. Dr. Stokes gives several cases in illustration of this plan of treatment. In the first he was unsuccessful, which he ascribes to the exhibition of purgatives, from his mind being warped by an early and unfounded prejudice as to the necessity of evacuations from the bowels. In another, after a moderate leeching, a grain of solid opium was given every hour without inducing the slightest affection of the brain, though the patient took, in the course of eight days, one hundred and five grains of opium, exclusive of opiate injections administered with the object of checking a severe diarrhoea which set in for three or four days.

Dr. Stokes has subsequently treated cases of common peritonitis with opium, where bleeding was inadmissible, and has had no reason to change his high opinion of its powers; and further proposes it as a remedy in cases of rupture of the bladder and uterus, in peritonitis after paracentesis, or succeeding to the operation for strangulated hernia, and in pneumothorax from pulmonary fistula.

The favourable results of the treatment of inflammation of the serous membranes by opium has led Dr. Stokes to employ it in the same condition of the mucous membrane, and under similar depressing circumstances. In a very interesting case of severe gastric fever, in which the abdominal symptoms ultimately became alarming from the supervention of severe diarrhoea, which every day threatened death from exhaustion, a grain of opium was ordered every hour, when the patient seemed in articulo mortis: this was continued for the first twelve hours without inconvenience, but with the effect of procuring refreshing sleep. Next day the remedy was repeated in the same dose every second hour; and from this time the improvement was rapid, and ended in final recovery.

Liberal doses of opium seem also to have had an excellent effect in a case of phagedenic ulceration of the throat. We have seen the most astonishing results from large doses of opium in sloughing phagedenic ulceration occurring in connexion with syphilitic symptoms in broken-up constitutions, such as is frequently observed in the lowest order of prostitutes.

Dr. Stokes has drawn the following conclusions on this subject:—1. that in cases of recent inflammation of serous and mucous membranes, where depletion by bloodletting or other antiphlogistic measures are inadmissible, and the system in a state of collapse, the exhibition of opium has a powerful effect in controlling the disease: 2. that under these

* Clinical Observations on the Exhibition of Opium in large doses in certain cases of disease, by William Stokes, M.D. one of the Physicians to the Meath Hospital.

circumstances, the remedy may be given in very large doses, with great benefit and safety : 3. that its effect, then, is to raise the powers of life and remove the local disease : 4. that the poisonous effects of opium are rarely observed in these cases ; the collapse and debility of the patient appearing to cause a *tolerance* of the remedy.

Acute pain may sometimes render the exhibition of opium necessary, even in the acute stage of inflammation. When the pain is so excessively violent as to constitute the most prominent symptom of the disease, and has resisted full depletion and other active remedies, its continuance tends greatly to aggravate the inflammatory action, and may even induce a fatal prostration of the vital powers. Under these circumstances, the subjugation of the pain becomes the most pressing indication, and this is to be effectually accomplished by the administration of opium in doses of from one to two and even three grains. This plan of treatment has proved eminently beneficial in severe cases of peritonitis, of sciatica and acute rheumatism affecting the heart. In those cases attended with extreme pain, two grains of opium may be given at first, and one grain every hour until the pain has subsided. It is necessary that the dose should be increased in proportion to the violence of the pain, and that the remedy be cautiously continued, until it has made a decided impression upon the nervous system, in order to procure the relief intended. It is well known that very large doses of opium are well tolerated when the nervous system is much excited ; but to guard against any injurious effect of this remedy on the brain, a cold lotion may be applied to the forehead, or if necessary to the whole scalp.

There is another condition of the system in which opium is extremely beneficial, viz. in exhaustion from loss of blood. There are some individuals who do not bear bloodletting well even when it is necessary ; in other cases, blood may be abstracted under mistaken views of the nature of the disease, or it may happen that more blood has been taken away than the symptoms either warranted or required.

In those cases of exhaustion arising from the effects of loss of blood, opium, with nourishment and cordials, is the best plan of restoring the patient.

There are some inflammatory diseases in which opium cannot with advantage be prescribed. In inflammation of the brain, it is a doubtful remedy even after the more active symptoms have been reduced. Indeed, in all acute diseases in which the brain is primarily or secondarily affected, the exhibition of opium requires great circumspection. It not unfrequently happens that when the more urgent symptoms of cerebritis have been overcome, the patient continues restless and wakeful, with a cool skin, soft clean tongue, and rapid soft pulse. These symptoms are often decidedly ameliorated by a full dose of opium. In inflammation of the mucous membranes, which generally terminates by an increased secretion, opium, from its tendency to check this salutary process, should be withheld, unless special

circumstances arise to render its exhibition imperative.

Of the other remedies of this class our individual experience does not warrant us to say much in terms of praise.

Digitalis, which was formerly so much extolled for its anti-inflammatory powers, is now rapidly falling into disuse. Though it certainly exerts a peculiar effect on the heart's action, its uncertainty and the length of time which elapses before it produces any decided impression, have tended much to impair the confidence which was at one time reposed in its efficacy in controlling inflammation. We have seen it given in very large doses (ten drops every half hour), and though it lowered the frequency of the circulation, it seemed in many instances to exert scarcely any control over the local disease. From what we have personally observed, therefore, we should not feel inclined to recommend the employment of digitalis as an anti-inflammatory remedy.

Colchicum is certainly efficacious in checking gouty and rheumatic inflammation. Some years ago this remedy was much used as a contro-stimulant in visceral inflammation, and was by some imagined to be little inferior in power to bloodletting. These sanguine expectations, however, have not been realized, and at present the administration of colchicum is almost entirely confined to the specific inflammation of gout and rheumatism, in which cases, we have prescribed a pill containing the acetic extract of colchicum (gr. i.) and extract of hyoscyamus (gr. iii.) every eight hours with excellent effects.

Among the remedies resorted to with the view of resolving inflammation, antimony has always been held in high estimation. Since its first introduction by Paracelsus, antimony has enjoyed more varied reputation in the treatment of acute diseases than any medicine in the *Materia Medica*. After it had been declared a most valuable remedy in many formidable disorders, it was denounced a poisonous medicine, and interdicted under very severe penalties by the French Parliament in 1566. In later times, however, it has been again brought into use, and within the last century has been prescribed as a most powerful antidote to almost every form of febrile disease. Various forms and preparations of this mineral have been from time to time introduced, but after repeated trials of their efficacy only two have been retained. These are the antimonial powder, pulvis antimonialis of the London Pharmacopœia, and the tartarate of antimony and potassa. The virtue of the antimonial powder is not only doubtful, but according to the experience of some physicians it appears to be positively inert, 130 grains having been given by Dr. Elliotson three times a day without producing even nausea. Dr. Thomson has satisfied himself from experimental investigations that the composition of the antimonial powder, and that of James's powder, which the former was intended to imitate, are totally dissimilar. This excellent pharmaceutical chemist states as the reason, that the antimony in James's powder is in the form of a soluble *protoxide*, while that in the

pulvis antimonialis of the *Pharmacopœia* is in the state of an insoluble *peroxide*; and from the ascertained fact that the more soluble the salts of antimony are, the more certain and powerful is their effect on the living body, the cause of the inertness of the one, and the more certain efficiency of the other, is thus explained.

Sometimes the skin becomes moistened, or the bowels gently purged by small doses (two or three grains) of James's powder given every four or six hours. More generally, however, it does not produce any sensible evacuation, the pulse becoming softer, and the skin more cool under its use. It is more efficacious when combined with calomel or blue pill, or occasionally with opium, when there is pain. Thus, after general or local bleeding, a pill containing two grains of calomel or blue pill, the same quantity of James's powder, and a quarter or half a grain of opium, may be given every three or four hours with decidedly good effects, every alternate pill being followed by a saline aperient, should the state of the bowels require it.

The tartarate of antimony and potassa (tartar emetic) is the preparation in most general use. It is seldom exhibited as an emetic, as the action of vomiting in inflammatory diseases is deemed prejudicial, at all events until the general excitement is reduced by bloodletting.

Stohl, however, recommended emetics in pneumonia. We are also told by Laennec, that Riviere vomited his patients in pneumonia with tartar emetic daily, or every second day; and that Dumangin, physician to La Charité, followed this plan, and though he seldom combined bloodletting with it, that his practice was quite as successful as that of Corvisart, who bled much in that disease. Laennec concludes that in these cases, the good effects of the tartar emetic are to be ascribed to the derivation exerted on the intestinal canal.

This mode of treatment still prevails in many parts of the continent, especially in France, as appears from memoirs which have recently emanated from the French press.*

From the well known effects of continued nausea in depressing the heart's action, nauseating doses of tartar emetic are frequently administered in inflammation, in conjunction with other antiphlogistic measures. For this purpose, a quarter of a grain of tartar emetic may be given in solution every two or three hours. The first two or three doses generally produce vomiting, but afterwards constant sickness is the only effect observed. By this mode of administration, the sub-acute forms of inflammation are often resolved, and in feeble habits, when the disease is little under the control of general or local bleeding, this mode of administering antimony is often followed by the most beneficial effects. The more slow or insidious forms of pulmonary inflammation, or the progress of tubercular disease may also often be checked by administering antimony in nauseating doses.

In still more minute quantities, (one-sixth or one-eighth of a grain every three hours,) tartar

emetic acts as a diaphoretic. This mode of administering antimony in inflammatory diseases was extolled by Cullen, and his example was followed by his pupils. It is seldom, however, prescribed alone, but in combination with other remedies of this class, more generally the saline diaphoretics.

Antimony has been at times exhibited in very large doses as an anti-inflammatory remedy, more particularly in Italy; indeed the large doses in which it has been administered by some continental physicians so astonished British physicians, that the accounts inserted in the foreign journals were at first discredited by many, while others supposed that there was a material difference in the chemical composition of the tartar emetic. It has, however, been proved by chemical analysis that there is no essential difference between the Italian and British preparations, besides that the formula given in the respective *pharmacopœias* is nearly alike.

The practice of giving large doses of tartar emetic was revived in Italy by Rasori, who, after embracing and widely disseminating the doctrines of Brown, had an opportunity of witnessing their fallacy in the treatment of an epidemic fever, which broke out at Genoa in the year 1799 and 1800. The application of the Brunonian principles to the management of this epidemic was attended with such fatal results, as to induce Rasori to change entirely the mode of treatment, and to substitute antiphlogistic measures. The practice of *contro-stimulus* which was pursued consisted in bloodletting, followed by large doses of tartar emetic, four, six, eight, or more grains being given in the course of the day in any agreeable vehicle. The success of this treatment was as great as the previous plan had been fatal, and had an important influence in subverting the untenable theories of Brown in the north of Italy. It also induced Rasori to employ the tartar emetic in other acute diseases, more particularly in peripneumony. From the memoir which he published on this subject, (the translation of which afterwards appeared in the *Archives Gén. de Méd.* for 1824,) it appears that after one or more bleedings, or without this evacuation, according to circumstances, he prescribed twelve grains of tartar emetic at intervals daily, which was repeated during the night. If the disease had made considerable progress, he began with twenty or thirty grains, increasing the dose daily till one or even several drams were taken in the course of twenty-four hours. The result of this practice in the hands of Rasori was encouraging. Of eight hundred and thirty-two cases of pneumonia treated by the tartar emetic, one-hundred and seventy-three only died. It was subsequently prescribed by most of the Italian physicians, some of whom published the results, from which it appears to have been even more successful in their hands.

Laennec was induced from these flattering accounts to make trial of it, but at first restricted it to cases of apoplexy. Having occasion some time afterwards, however, to attend two cases of peripneumony in which he thought it inexpedient to resort to venesection, he determined to make trial of the tartar emetic; both patients

* *Mémoire sur les fluxions de poitrine*, par Louis Valentin, M.D. Clinique Méd. de l'Hôtel Dieu de Rouen.

rapidly and unexpectedly recovered, so that he was encouraged to give it in other cases. Laennec did not prescribe it in the large doses recommended by Rasori; indeed his mode of administration is so judicious that it has been generally adopted. The following is a summary of the manner in which Laennec employed the tartar emetic in the treatment of pneumonia. As soon as the existence of the disease was recognised, and the patient was able to bear venesection, blood was first taken from the arm, unless in cachectic or debilitated subjects, in which it was deemed advisable to dispense with this evacuation. Immediately after bleeding, one grain of tartar emetic dissolved in infusion of orange-leaf was directed to be taken and repeated every second hour for six times, after which the patient was allowed to remain quiet for seven or eight hours, if the symptoms were not urgent, or the patient disposed to sleep. If the inflammation had already made considerable progress, the same dose was continued uninterruptedly until there was decided amendment.

It was seldom necessary to give a larger quantity of the tartar emetic, though in extreme cases as much as a grain and a half, two grains, or two grains and a half, were prescribed at the same intervals. Many patients were found to bear these doses of the tartar emetic without either vomiting or purging being induced: more generally, however, it excited vomiting or purging for the first day, but this effect soon passed off, and the *tolerance* (power of bearing the remedy) became established often within twenty-four hours from the time of its first administration. It was even occasionally necessary afterwards to prescribe gentle aperients to keep the bowels open. It was observed also that the tartar emetic was most efficacious when it did not produce any sensible evacuation; and that, although severe vomiting and purging are by no means desirable, the cure of the inflammation was often very satisfactory, when the stomach and bowels were much irritated by the remedy. This may often be checked by combining with the tartar emetic a small quantity of opium. Laennec recommends the addition of one or two ounces of syrup of poppy to the six doses to be taken in twenty-four hours. We have found the irritation very much allayed by adding the dose of the tartar emetic to the common effervescing mixture, to which a few drops of laudanum may, if necessary, be added.

At the end of a few hours, seldom beyond twenty-four, such a decided improvement in the symptoms takes place, that both the patient and the practitioner are encouraged to persevere with the medicine till resolution of the inflammation be effected, when the medicine should be withdrawn gradually by giving it at more distant intervals. It is singular how patients become accustomed to tartar emetic when restored to convalescence. Laennec states that when they are taking their usual allowance of food, nine, twelve, or even eighteen grains of the emetic tartar may be taken daily without their being at all aware of any medicine being given. This is in opposition to the opinion of Rasori, who considers the *tolerance* to be owing

to the excess of stimulus which exists in the system and produces the disease; consequently, whenever this is destroyed by the contro-stimulant effect of the tartar emetic, the tolerance, were this theory correct, should cease, which is certainly in direct opposition to our own experience. We have observed in some cases of pneumonia treated by tartar emetic, that when the patient could bear a grain every second hour, twenty drops of the antimonial solution produced copious vomiting, shewing that this medicine is less emetic in large than in small doses.

Laennec has detailed shortly the several diseases in which the emetic tartar has been found successful in his hands. These were, 1. pulmonary inflammation; 2. inflammation of serous membranes, though he did not appear to place great value on its powers in this class of diseases; 3. hydrocephalus; 4. phlebitis; 5. acute chorea; 6. articular rheumatism; 7. severe ophthalmia; 8. apoplexy; 9. acute dropsy.

No satisfactory explanation has been offered of the mode in which tartar emetic affects the resolution of inflammation. It appears not only to check the progress of inflammation, but to cause the absorption of inflammatory effusions. Laennec affirmed that he had observed, in a case of articular rheumatism, well marked fluctuation of the knee-joint disappear in the course of six hours by the use of this medicine.

The value of large doses of tartar emetic, as a powerful anti-inflammatory remedy, is now established by the united experience of the most distinguished British and continental practitioners. In our own hands, we have seen the most surprising effects produced by it when administered according to the mode proposed by Laennec. We have never found it necessary to exceed twenty grains in twenty-four hours, and when the remedy is at all likely to be beneficial, this quantity need not be exceeded. There are few cases of inflammatory disease in the early stage, which do not yield to prompt bleeding, followed by a few doses of tartar emetic; and in cases which have been so long neglected that the period for bloodletting has been allowed to pass over, it affords the chance best of grappling successfully with the disease.

These are the general measures on which our chief reliance should be placed for the removal of inflammation. There are other points of minor importance to be attended to; for example, the thirst is to be allayed by cooling sub-acid drinks, containing lemon-juice, cream of tartar, or a solution of the pulp of tamarinds. It is also sometimes expedient to endeavour to diminish feverish heat by the free admission of cool air, by light bed clothes, and by administering refrigerants, such as citrate of potash, acetate of ammonia, or nitre. These measures, however, are not to divert the attention from the more active remedies.

The propriety also of removing every source of irritation is obvious; not only is the exciting cause to be ascertained, and, if practical, removed, but excitement of every kind must be withdrawn; hence in visceral inflammation the greatest quietude of body and mind is indispensable. When, therefore, the inflammation is seated in an external part, all use of

the organ must be avoided, and such position adopted, as will be least likely to favour the circulation of the blood towards the inflamed part.

Every kind of food which has a tendency to excite the circulation must be avoided; the very mildest farinaceous aliment being best adapted, and even this should be given in small quantities at stated intervals.

We shall next shortly allude to the local treatment of inflammation.

In all diseases attended with excitement, the free application of cold is decidedly beneficial. In inflammation of the brain, after depletion, the application of cold evaporating lotions, or bladders filled with pounded ice, not only reduces the morbid heat of the scalp, but diminishes the vascular action in the brain. The most powerful mode of applying cold to the head is the *cold dash*, which we regard as little inferior to bloodletting itself; and when the general powers are too weak to render the abstraction of blood to an adequate extent expedient, it is the most effectual mode of arresting the inflammatory action.

In the subacute or chronic form of inflammation of the lung, more particularly in that slow insidious form which attends the formation or progress of tubercles, the local application of cold tends materially to check the progress of tubercular disease. For this purpose the chest is to be sponged daily with vinegar and water, (at first tepid, and afterwards cooled down to the natural temperature,) and after being rapidly dried, the skin should be well rubbed with a coarse towel or flannel. This mode of applying cold has also the advantage of removing or diminishing the susceptibility to cold, which renders the consumptive invalid so liable to returns of the inflammation. In inflammation of the abdomen, cold applications have been recommended by some practitioners. Some years ago Dr. Sutton strongly advocated this practice in peritoneal inflammation, and detailed several interesting cases in which the local application of cold was decidedly beneficial. From Dr. Sutton's observations, this practice appears to be peculiarly adapted to the chronic stage of peritonitis, when the symptoms are not such as to require bloodletting.*

In external inflammation, the application of cold lotions forms an essential part of the antiphlogistic measures. For this purpose a solution of acetate of lead, or a lotion consisting of equal parts of the acetate of ammonia, alcohol, and water, may be employed. These may be used cold or tepid, according to the feelings of the patient.

Warm applications are often very beneficial in inflammation. The warm bath, by producing a powerful determination of blood to the external parts, is often employed with great advantage, more especially in inflammation of the abdominal cavity. For this purpose the temperature of the water should not be too high, (not exceeding 98°,) a greater degree of heat proving a stimulus, and thus increasing the inflammatory action.

* Tracts on Delirium Tremens, on Peritonitis, &c. by Thomas Sutton, M.D. 1813.

The partial application of heat in the form of fomentations is often a powerful mode of reducing inflammatory action, and at the same time of relieving pain. We have an illustration of this in the beneficial effects of the vapour arising from warm water, or the decoction of poppy or hyoscyamus in ophthalmia, and in various forms of external inflammation. Warm fomentations properly applied often prove valuable applications also in internal inflammation. We have often observed excellent effects from them in pulmonary inflammation after general or topical bleeding, and in abdominal inflammation this practice is so beneficial that it is seldom if ever omitted.

The different forms of counter-irritation are employed in certain stages of inflammation with great advantage, after the activity of the symptoms has been subdued. When this has been accomplished, should there be pain, the application of a sinapism or blister to the neighbourhood of the inflamed organ will frequently remove it, and when the inflammation has passed into the chronic form, the repeated application of blisters is decidedly beneficial. Great care, however, should be taken that local stimulants be not applied until the active stage of the disease has been overcome. The principles on which the application of counter-irritants should be employed have been so fully discussed in the articles COUNTER-IRRITATION and DERIVATION, that it is unnecessary in this place to go more into detail. We may, however, just advert to the practice of applying blisters when inflammation has receded from a part it had just occupied, and fixed on another organ, as happens now and then in gout and rheumatism. It has been recommended to apply a blister near the seat of the former disease with the view of recalling the inflammation, but we agree with Mr. Lawrence, that it is better to attack the inflammation vigorously in its new quarters, than to attempt to entice it back to its old seat.

It is scarcely necessary to state, that in determining the measures which may be necessary for the treatment of inflammation, we must bear in view the particular circumstances with which it is accompanied, or which may arise in its progress. For example, we are to consider not only its duration, and degree or amount, but the age and constitutional powers of the individual, and the effect of such measures as may have been adopted. When inflammation occurs in a feeble or exhausted habit, (and the local symptoms may in such cases be intense,) the treatment must be less active. Perhaps a small bleeding may be hazarded, but in general it will be more safe to trust to local bloodletting, with mercury and opium. It is often necessary in such cases to adopt local antiphlogistic treatment, and at the same time to give general support by animal nourishment. Even wine may be occasionally required.

There is another point of great practical importance connected with the treatment of inflammation. We frequently observe, after the employment of active measures, that the symptoms, though much modified, continue; the general symptoms may even be entirely re-

moved, but the local disease is still perceptible; a degree of passive inflammation or local congestion remains, which a further extension of bleeding or purging infallibly aggravates. This is often observed in ophthalmia, and did not escape the observation of Hunter. In other instances the measures adopted produce exhaustion accompanied with morbid irritability, which it is often exceedingly difficult to distinguish from inflammation. Both the local and general symptoms will, however, afford some assistance. The pulse, though quick, will be found soft and compressible, the skin cool, and there is little if any thirst. The local symptoms are slight; there is often very little pain, and when there is, it is transient. What is to be done under these circumstances? Stimuli may reproduce the inflammation; bleeding and other depleting measures will aggravate the symptoms. It is most prudent in these cases to try cautiously fluid nourishment, with a little wine in sago or arrow-root; and if the state of the local symptoms admit of local detraction of blood, a few leeches may be from time to time applied. In short a combination of treatment answers best.

In the treatment of congestions of blood—a subject of great importance, though involved in obscurity—we agree with the precepts laid down by Dr. Barlow. If the congestion arise in a plethoric habit, it is evident that general antiphlogistic measures, more especially bleeding, purging, and abstemious diet, must be resorted to. This plan, however, must not be carried too far; it is sufficient to take off the pressure from the circulation in order to overcome the plethora. Over-bleeding, from the reaction which follows, and the weakness it induces, brings on this very state.

When the local congestion is unaccompanied with general fulness, or when it is the result of irritation, local depletion is to be adopted in preference to the general measures, which are indispensable when plethora exists: indeed, as Dr. Barlow has well remarked, general depletion is not only unnecessary but injurious, enfeebling the system, and awakening those efforts by which the congestion would be naturally relieved. (See CONGESTION OF BLOOD.)

The other measures which in congestive affections may be employed in conjunction with bloodletting, or alone when this evacuation may be dispensed with, are mild purgatives, diaphoretics, warm bathing, counter-irritation, and low diet. These several measures must be varied, and repeated more or less frequently according to circumstances.

Congestive affections, both of an acute and chronic character, are not unfrequently combined with general debility; and there are cases in which a mixed plan of treatment is often indicated, and the management of which requires generally much tact and caution. The general debility is sometimes the *primary* cause of the acuteness and persistence of the congestion; and if such active antiphlogistic remedies be used as increase the general debility, they will inevitably have the effect of aggravating the local complaint. While, there-

fore, it may be advisable, in such cases, to keep the local congestion in check by small topical bleedings, counter-irritation, fomentations, poultices, &c. it is often necessary to strengthen the constitution by the use of tonics, generous diet, and change of air.

In many cases of chronic congestions in which the bloodvessels are relaxed, the resolution of the congestion is often greatly favoured by the exhibition of tonics and stimulants. We may mention, for instance, the good effects of various tonics in chronic catarrhal affections, and in some other chronic pulmonary diseases.

In cases of habitual determination of blood, and of a tendency to attacks of congestion of one particular organ, such as the brain, lungs, &c. bleeding by revulsion (or at a remote distance from the organ affected) occasionally repeated, together with great attention to the regulation of diet, and the general management of the system, is found more effectual than depletion in the neighbourhood of the organ, which often induces an increased disposition to an undue influx of blood, although it may procure momentary relief.

Chronic inflammation differs from acute only in degree. The duration of the disease is of little consequence compared with its intensity. It should also be kept in mind that inflammation which has been for some time in a dormant or chronic state, sometimes becomes suddenly acute, and may require vigorous measures for its removal.

In the treatment of chronic inflammation, there being no constitutional excitement, general bloodletting is seldom necessary, local bleeding by cupping or the application of leeches being generally sufficient, unless there be a degree of feverishness, or the inflammation be seated in an organ over which local bloodletting exerts little controul, when the abstraction of a few ounces of blood from the arm is preferable. The bowels are to be thoroughly cleansed by purgatives, and afterwards a general action should be kept up by alterative doses of mercurials with the milder kinds of aperients, such as rhubarb with manna and Rochelle salt.

Counter-irritation is especially necessary in chronic inflammation. Blisters are less effective than the more severe kinds of counter-irritants, such as tartar emetic ointment, or a plaster made of equal parts of Burgundy pitch and yellow wax, to which a scruple or half drachm of tartar emetic (according to the size) is to be added. Either the tartar emetic ointment or plaster bring out a copious eruption of pustules, which greatly relieves the chronic forms of inflammation. Sometimes a seton, caustic, issue, or the moxa, is employed with great advantage.

In all cases of inflammation, whether acute or chronic, the regulation of the diet is of essential importance. In acute inflammation the mildest food only is admissible; in the chronic, nourishment may be more freely allowed. Indeed it is often necessary to allow moderate support while local bleeding and other measures are employed. Pure air is of most essential consequence in all acute diseases, and often exerts a most decided influence in the treatment

of low kinds of inflammation, which it is often difficult to remove in certain localities.

The general principles by which the treatment of inflammation is to be regulated having been considered, we proceed to state what is necessary to be done when any of its effects or terminations have taken place.

It is necessary, however, to bear in mind, that although the inflammation may have produced either of the morbid changes alluded to, the inflammatory action may be still going on, so that it is necessary to watch the primary disease, as well as its effects. For example, in pleurisy and peritonitis, the liquid effusion in the pleural or abdominal cavity does not necessarily imply that the inflammation of the pleura or peritoneum has ceased: on the contrary, we almost invariably find it necessary in such instances to combat the inflammation on which the effusion depends, at the same time that we attempt the removal of the effused fluid. It is not uncommon to observe, that as the local inflammation is reduced, the effusion disappears simultaneously, or very soon after: in such cases the effusion does not depend, as has been too generally supposed, on diminished action of the absorbents, but on the increased quantity of fluid which is effused from the inflamed surface.

The sudden relief which often follows from bloodletting judiciously employed in cases of acute dropsy is thus explained; and also, how venesection frequently removes dropsical effusion when diuretics in every form and combination have failed. When effusion follows inflammation of a more chronic character, more especially when the powers of the individual are low, it becomes a point for consideration how far any form of bloodletting may be advantageously adopted. In such cases the local abstraction of blood, or other local antiphlogistic measures, may be advantageously combined with such remedies as are calculated to effect the removal of the effused fluid. The various means which are to be employed, as well as the circumstances which are to regulate their administration, have been already considered in the article DROPSY, to which we refer.

The effusion which takes place as a consequence of inflammation of any of the three cavities, may proceed to such an extent as to embarrass seriously the functions of the contained organs, and even ultimately to destroy life. This has led to an attempt to evacuate the effused fluid by an opening. Such an operation, however, is not always practicable, as, for instance, in the effusion which is the effect of acute hydrocephalic inflammation. A few practitioners of more than ordinary boldness have, however, ventured on tapping the cranium in *chronic hydrocephalus*; but though in some recent examples this operation has been successfully performed, we fear the small average proportion of cases in which it has succeeded will scarcely give general encouragement to hazard it.

When effusion to a considerable amount takes place in the pleural cavity, there is little hope of deriving any permanent advantage from the employment of internal remedies administered with the view of promoting the absorption of

the effused fluid. In such cases the chest has been tapped, and with such favourable results, that this operation can no longer be viewed as a hazardous attempt, but the only means of saving the sufferer from indescribable suffering and ultimate death. (See EMPYEMA.)

When peritonitis terminates in effusion, the effect of evacuating the fluid is doubtful: in many instances the fluctuation is not perceptible during life; and even were the fluid detected, more benefit is derived from occasional leeching, counter-irritation of the abdomen, mercury, and diuretics. By a steady perseverance in these measures, abdominal effusion succeeding to peritonitis has been frequently removed under most unpromising circumstances.

When inflammation has terminated in suppuration, similar principles must regulate the treatment, the extent of purulent formations being often materially diminished by a continuance of measures calculated to abate the inflammatory action. The kind and extent of these measures must depend on the active or passive nature of the local as well as constitutional symptoms, the object in every case being if possible to arrest, or if this be impracticable, to diminish the extent of the purulent formation, and afterwards to promote either the absorption or evacuation of the matter. If the suppurative process be accompanied by local or general symptoms, as in *phlegmonous abscess*, it is evident that a persistence in antiphlogistic measures, including general or local bloodletting if necessary, may be required till the excitement is subdued. It is well known also, that a removal of the inflammatory action frequently takes place in an organ after matter has formed, just as acute may supervene on chronic inflammation, or as the inflammatory process may be suddenly renewed in a part recently inflamed. The necessity, therefore, of watching the progress of inflammation in organs in which purulent formations have occurred, is apparent, though the attention of practitioners, it must be confessed, is too often almost exclusively directed by the local measures which are best calculated to assist the evacuation of the purulent matter.

On the other hand, when suppuration takes place in feeble habits, general antiphlogistic measures must be employed with great caution, even though there be evidence of local excitement. In these cases, a moderately stimulant plan of treatment, consisting chiefly in nutritious diet, a moderate use of wine and tonic medicines, is often more successful; and should the local affection indicate too great excitement, this may be moderated by small detractions of blood from the neighbourhood of the part, and such other local measures of an antiphlogistic kind as circumstances may require. In short, the practitioner must have in view, on the one hand, not to retard a salutary process, nor, on the other, to increase or renew the action by which the suppuration has been induced.

When suppuration succeeds to phlegmonous inflammation of the external parts of the

body, various topical applications are found useful. Warm applications are most suitable not only from their soothing, but from their supposed power of promoting the process of suppuration. Fomentations of simple warm water, or of decoctions of anodyne or emollient substances, are to be frequently applied, and the part afterwards covered with a large poultice of bread and water, or of linseed flour, some contrivance being adopted to prevent the escape of the heat and moisture. These applications are to be frequently renewed, as soon, indeed, as they become cool, the principal benefit being derived from their warmth and moisture.

When fluctuation can be detected, whether the purulent matter be collected in a distinct cyst or abscess, or be diffused in the cellular tissue, it becomes a subject of consideration whether the pus should be evacuated by an opening made into the part, or be allowed to discharge itself by the gradual process of ulcerative absorption or spontaneous rupture.

If the abscess be situated near the surface of the body and at a distance from any important organs, surgical interference may generally be dispensed with. There are some circumstances, however, which render it advisable to open abscesses as soon as matter can be detected. For example, when the abscess forms in the neighbourhood of an organ important to life, such as the larynx or trachea; near a large joint; in the vicinity of any of the great cavities; when the matter is deep-seated, or being resisted by an unyielding texture, becomes diffused among other parts where less resistance is offered, as in abscess beneath the fascia covering muscles, in the sheaths of tendons, or under the periosteal covering of flat bones—an early opening should be made for the discharge of the purulent matter. The cavity of the abscess becomes afterwards gradually obliterated by the process of granulation and cicatrization, but this stage of the curative process frequently requires the attention of the surgeon.

The treatment of chronic suppuration differs in many respects from that of the acute. It is often surprising how little constitutional disturbance precedes or accompanies these chronic abscesses, which have sometimes been observed to give no indication of their formation, till attention has been directed to an indolent swelling, which on examination is found to contain fluid. They are frequently observed in individuals of an unhealthy constitution, and more especially in those of a strumous diathesis. Hence, in the treatment, the improvement of the general health must form a more prominent feature than even the local management of the abscess.

Chronic abscesses evince a great disposition to increase in size, but the matter has a tendency rather to become diffused than to approach the surface, or, as it is termed, *to point*. The propriety, therefore, of opening them requires, in general, little consideration, though the mode in which this is to be done is a matter of greater nicety. Mr. Lawrence, in his lectures on inflammation, has very clearly pointed out the local and constitutional effects

which follow when these chronic abscesses are opened in the same way as a phlegmonous abscess. If an aperture be made so as to evacuate the matter, and a poultice be afterwards applied, as is the practice in phlegmonous abscesses, the entrance of the air produces decomposition of the matter; the surface or cyst of the abscess inflames; the purulent secretion is altered, becoming thin, fetid, and very irritating to the parts with which it comes in contact. The constitutional disturbance which is thus excited aggravates the local disease, which, in its turn, reacts on the constitutional irritation to such a degree as seriously to disturb the general health, and frequently to destroy the patient.

The mode of treating chronic abscesses adopted by the late Mr. Abernethy obviates the risk of inflammation of the cyst, and the constitutional effects to which it gives rise. This consists in making a small oblique opening into the abscess so as to allow its contents to escape, the ingress of air being carefully prevented; the aperture is then to be closed, and pressure applied so as to allow of its uniting by adhesion. The object of this practice is to diminish the cavity of the abscess, so that, after it has become contracted, it may be again opened, and afterwards treated in the same way as a phlegmonous abscess, and at the same time to obviate the constitutional irritation which arises from exposing the cyst of a large abscess to the action of the external air.

This mode of treatment is, however, not invariably successful; the cyst often continues to secrete pus so as to distend the abscess to its former size, or, if it be diminished, a fistulous opening leading to a large cavity remains. In these cases, surgeons have succeeded in producing inflammation and adhesion of the cyst of the abscess by passing a seton through it, or by injecting irritating fluids.

The general health is to be improved by nutritious diet, vegetable or mineral tonics, and residence in a pure atmosphere.

The treatment of ulceration must depend on its local or constitutional origin, the acute or chronic character of the inflammation by which it is accompanied, the causes by which it is induced, and the structure in which it occurs.

1. Ulceration may be strictly a local affection, as when it arises on an external part of the body from an external cause, such as a wound or other kind of injury. In this case the ulceration may be either accompanied with little or no inflammatory action, or with considerable local as well as constitutional disturbance. It is evident that in the former, mild local applications, and avoiding exercise or use of the part, will speedily affect a cure; while in the latter, antiphlogistic measures, even general or local bleeding, must be combined with topical applications.

2. When ulceration arises from constitutional causes, in addition to the local treatment it is necessary to attend to the general health. Thus, when ulceration of an external structure arises from syphilitic, syphiloid, cancerous, scorbutic, or scrofulous diathesis, it is in vain to attempt to heal the ulceration by local

measures alone; or should these succeed, the cure cannot be considered permanent until the particular constitutional malady be subdued.

3. Though almost every tissue of the body is liable to ulceration, it occurs more frequently in the skin and mucous membranes. In the former the treatment is often tedious, depending in many instances on the state of health and previous habits of the individual. The local treatment requires attention also to the kind and extent of the local inflammation: this is in some cases of an active inflammatory character; in others it is of a low or chronic kind, the one demanding an antiphlogistic, the other a stimulant plan of treatment. It is inconsistent with this outline to enter more minutely on the treatment of ulcers, and as this belongs more properly to the province of surgery, we beg to refer to the writings of Home, Lawrence, Thomson, Cooper, Bell, Brodie, and others, for much valuable information on this subject.

Ulceration in mucous membranes is more common in some situations than in others, the gastro-intestinal mucous membrane being by far its most frequent seat. We have repeatedly alluded to the latency of gastro-enteritis, and even when it proceeds to ulceration, the symptoms are no less equivocal. Hence arises the uncertainty of any method of treatment except that which tends to arrest inflammation in this tissue. We do not affirm that ulceration of mucous membranes does not cicatrize: this has been demonstrated by the most satisfactory process, not only in genuine cicatrix of ulcers of the stomach and colon, but even in the small intestines. The exhibition of mineral tonics and astringents—sulphate of copper, or the superacetate of lead, in combination with opium,—in intestinal ulceration have been found successful, though some physicians speak of the more powerful vegetable tonics, sulphate of quinine, strong infusion of catechu or logwood, as equally efficacious.

When ulceration occurs in the bucco-pharyngeal membrane from the syphilitic or syphilitoid poison, the treatment must be entirely constitutional; therefore mercury, sarsaparilla, and nitric acid must be given according to circumstances. Phagedenic ulceration of the genital organs requires the application of a powerful escharotic, for example the concentrated nitric acid. We have seen the action of this *specific* in those cases powerfully assisted by liberal doses of opium, to the extent even of a scruple in the twenty-four hours.

Mortification is a frequent termination of inflammation, but it arises also from a variety of other causes. It is obvious, however, that in this place we can only consider the treatment of that form which is the effect of inflammation, and refer for information as to the measures to be adopted, when it takes place from other causes, to various articles in this work, and to the article MORTIFICATION.

The general principles on which the treatment of mortification originating in inflammation is to be conducted, vary according to the circumstances with which it may be associated; for it is inconsistent to suppose that one general

rule can be applicable to every case that may occur. Dr. Thomson has justly remarked, there can be no general plan of treatment equally suitable to the differences which occur in the seat, form, progress, and state of the disease, nor to the various affections of the general system by which it is invariably accompanied.

In all cases of mortification there are some circumstances to be considered before any plan of treatment is determined. 1. Mortification, in respect to its seat, is distinguished as it affects an internal or an external part. 2. It is necessary to determine whether the mortification arise spontaneously, (i. e. from some causes connected with the general system, which are not very obvious,) or whether it originate from some external cause or local injury: and, 3, whether it be of an acute or chronic character.

When inflammation of an external organ terminates in mortification, it is almost invariably fatal, the acute inflammation of which it is the effect being often of itself sufficient to destroy life; when it is not, the system is seldom able to withstand the additional irritation which the mortification induces. If, therefore, the violence of inflammation in an internal organ be likely to terminate in gangrene, the only indication of treatment is to prevent its taking place by active antiphlogistic measures, since it is well known that death almost invariably follows mortification of an internal organ, unless, as very rarely happens, the gangrenous inflammation has stopped spontaneously, and the mortified parts have separated and been afterwards expelled by a natural outlet.

In every disease it is obviously necessary to ascertain and to remove, if possible, its causes; and this is no less important in mortification. When it arises from inflammation, it is necessary to discover whether this action still continues, or has abated or entirely ceased. If the inflammation still continues, it is proper to ascertain its degree, both as respects the general as well as the local symptoms; for we often find that there is considerable local action going on with very moderate excitement of the constitution. When the causes and degree of gangrenous inflammation have been ascertained, the object of the treatment to be adopted is to prevent mortification taking place; or if it have already occurred, to arrest its progress; and if seated externally, to promote the separation of the mortified from the living parts.

To fulfil these indications, the measures to be adopted must have reference to the acute or typhoid character of the symptoms. It is scarcely necessary in the present day to state that no reliance can be placed in the antiseptic medicines recommended by the older authors, on the mistaken idea that mortification depended on putrefaction or decomposition of the solids. Their principles of treatment consisted in endeavouring to prevent or arrest mortification by administering, internally and externally, medicines which were known to prevent the decomposition of dead animal matter. These were chiefly the more powerful vegetable and mineral tonics, and various local stimulants applied to the mortified parts. It is true that in certain states and stages of mortification

the same measures are in the present day employed, but on very different principles, no one attributing their good effects to a supposed power of preventing putrefaction by their chemical operation, but to their action as general corroborants or stimulants. The practical error committed by those who ascribed the advantages which occasionally resulted from the exhibition of these remedies, was not only in the principles on which they were administered, but in their indiscriminate adoption in every stage and form of mortification, even in cases which originated from acute inflammation. We shall presently shew that they have their value even among modern pathologists; and in stating our opinion, we wish to impress on the reader that we are desirous of guarding the inexperienced against erroneous principles of application, rather than against the remedies themselves.

In acute mortification, the general and local excitement require the adoption of antiphlogistic measures modified according to circumstances. General bloodletting, if the pulse be full and hard, and there be great local pain and redness, will be necessary, and must be repeated till the pulse become soft, and the other symptoms are moderated. The other parts of the antiphlogistic treatment, consisting of purgatives, saline diaphoretics, and abstinence from stimulating food, must be at the same time enjoined. These measures are necessary in the early stage of acute inflammation, not only to prevent mortification, but, when it has begun, to check its further progress. The extent to which bloodletting and the other antiphlogistic measures are to be carried requires nice discrimination, and especially reference to the age, powers, and previous habits of the individual, as well as to the stage of mortification. The pulse in these cases is often a fallacious guide, more especially when the mortification occurs in a vital organ. The practitioner must, therefore, consider rather its particular character with regard to fullness or hardness, than to frequency. If it be soft, though frequent, and if the skin be cool,—moreover, if the individual be of an irritable habit, and somewhat advanced in years, the lancet must be withheld, as under such circumstances detraction of blood would increase the irritability of the heart's action, weaken the patient, and favour the progress of the mortification. Such symptoms, which are often mistaken for inflammation, require attention to the state of the bowels, the moderate use of opium, the exhibition of mild nourishment, and the moderate use of wine. In other instances the state of the general as well as of the local symptoms indicates sub-acute inflammation—a condition intermediate between acute and chronic mortification, requiring a modification of the antiphlogistic treatment, according to existing circumstances. A full bleeding from the arm may be necessary or advisable, to diminish the velocity and force of the circulation, though, in many instances, this may be dispensed with; local bleeding by the application of leeches at a short distance from the mortified part, purgatives, antimonials, mercury, and low diet,

being generally sufficient to arrest the progress of the mortification.

When the treatment adopted has succeeded in abating the inflammation, and when the progress of the mortification is consequently arrested, further antiphlogistic measures must be suspended, and the powers of the patient reserved for what the system has yet to accomplish—the separation of the mortified from the living parts. In the external parts of the body this is indicated by a red line, which shews the boundary of mortification, and, at the same time, that the process has stopped.

A certain degree of inflammation is necessary to carry on the separation of the dead from the mortified parts; and if the powers of the system be feeble, it is evident that this salutary process cannot proceed. In this stage the patient must be supported, especially if advanced in years, by animal food in the form of strong broths or jellies, and in some cases wine and other diffusible stimuli may be given according to the indications. It is necessary to be very cautious, however, that these measures be not adopted too early or before the inflammatory action be sufficiently reduced, and if they seem to renew the inflammatory excitement, they must be administered in small quantities, or altogether withdrawn, and mild vegetable nourishment substituted. A similar tonic plan of treatment is requisite when the general fever assumes a typhoid type, which it frequently does very early: in these cases the mortification often proceeds with great rapidity, and the only chance of arresting it is by the liberal administration of stimuli, animal nourishment, cordials, and wine.

From the supposed virtues of the Peruvian bark in preventing or arresting mortification, it is necessary to allude to it more particularly. About a century ago it had acquired considerable reputation for its supposed antiseptic powers, and was consequently extolled as a remedy possessing great power in the treatment of mortification. It is probable, however, that its indiscriminate adoption led to frequent failures; it consequently fell into disrepute, and its exhibition is now confined entirely to mortification accompanied with typhoid symptoms, in which other remedies of a stimulant and tonic kind are found useful. It is obviously an improper remedy when there is inflammatory excitement, when there is derangement of the stomach and bowels, or when the mortification succeeds to inflammation produced by external injury. When it is indicated, the sulphate of quinine is the best form of administration, in doses of two grains repeated at suitable intervals. When either the bark in powder, infusion, or decoction, or the sulphate of quinine disagrees, or proves too stimulating, an infusion of some of the lighter vegetable tonics, *cascarilla*, *gentian*, or *calumbo*, may be substituted; to an infusion of either of these an aperient, such as the infusion of *rhubarb*, may be added, should the state of the bowels require the combination.

Opium, when administered in proper cases, is an invaluable remedy in mortification; it soothes pain, and diminishes the restlessness

and irritability with which mortification is so frequently accompanied, and often procures sleep. In the acute stage of mortification, it is improper until the excitement has been subdued; it may then be given at distant intervals in combination with calomel. One grain of opium combined with two of calomel in a soft pill may be given every six or eight hours, if there be pain, irritability, and wakefulness; and should this quantity fail to procure sleep, two grains of solid opium may be given once, or perhaps twice in the twenty-four hours. This remedy is more especially indicated should spasms or convulsions arise in the progress of the mortification. The late Mr. White of Manchester recommended, in spasmodic contractions and convulsions arising during mortification from external injury, large doses of musk and volatile alkali, which he asserted removed the singultus, subsultus tendinum, and convulsive spasms, while at the same time the mortification was stopped. We agree, however, with Dr. Thomson as to the doubtful efficacy of these remedies under the circumstances mentioned by Mr. White, more particularly as this eminent surgeon candidly confessed he had been disappointed in the effects of this combination, when it was tried in mortification arising from other causes.

When mortification on the surface of the body has terminated in sphacelus, the separation of the mortified from the living parts may sometimes be assisted by local applications. In former times, the practice of surgeons was to make incisions or scarifications through the dead down to the living parts, in order to apply stimulating and, as was supposed, antiseptic substances, such as turpentine, balsams, and even essential oils, regardless of the degree of local inflammation which already existed or might be produced by such applications. Mr. Samuel Cooper has very well remarked, that though such things are indeed really useful in preserving dead animal substances from becoming putrid, a very little knowledge of the animal economy is requisite to make us understand that they cannot act in this manner on parts still endowed with vitality; but on the contrary, that they must have highly prejudicial effects in the cases under consideration, by reason of the violent irritation which they always excite when applied to the living fibres.

Any local application is unnecessary, and often injurious before the mortification has stopped. This, as we have seen, is indicated by a defined red line, which shews the separation of the mortified from the living parts: the living portion adjoining the sphacelus assumes a red colour, ulcerative absorption commences, by which the mortified are gradually removed from the living parts.

The object of local applications is, 1. to soothe the local irritation; 2. to allay any excitement in the part that may arise; 3. to accelerate the process of separation when it proceeds too slowly; and, 4. to correct the fetor.

The most soothing application is a common poultice made of stale bread or lintseed flour and water, and in nine cases in ten this forms the best local application in mortification.

When the heat of a poultice produces too much irritation, a cold lotion, or if more agreeable to the feelings of the patient, a tepid lotion may be applied by means of one or two folds of linen. It should be remembered, however, that while heat increases the local action, cold, on the other hand, though it at first diminish or repress vascular action, when too long applied produces debility, and may be consequently injurious.

When it appears expedient to stimulate the living parts, several local applications are employed by surgeons. Mr. Lawrence recommends the nitric acid, of which from four to ten drops may be added to an ounce of distilled water, and lint moistened in this lotion applied to the part. The pyroligneous acid has also been applied with advantage, more especially in hospital gangrene. A liniment, composed of oil of turpentine and resinous ointment in equal proportions, is an excellent stimulating dressing in mortification. The mode of applying this liniment is to moisten lint in it when made warm by putting the vessel in which the liniment is contained in boiling water, by which it is soon liquefied. The lint soaked in this liniment is to be put on the part, which is to be afterwards covered with a large warm poultice. This dressing may be renewed once or twice a day or oftener, according to circumstances.

Various kinds of stimulating poultices have been recommended. The common yeast poultice, prepared by adding to the grounds of stale strong beer, as much bread crumb or lintseed flour as will make a poultice, answers very well: or some surgeons prefer the effervescing poultice, prepared by adding to an infusion of malt as much oatmeal as is necessary to form a poultice, and afterward mixing with it a tablespoonful of fresh yeast.

When the ulceration looks healthy, and the process of separation goes on satisfactorily, the stimulating ingredients in the dressings must be diminished or wholly withdrawn. Dr. Thomson has shown that the ulcerating surface is, in the progress of separation, liable to pass, under every mode of treatment, into the state of a painful and irritable ulcer; and in this state it may require to be treated with anodyne fomentations, or with poultices made of carrot, turnip, or fresh hemlock leaves. In these cases, as in sores from other causes, the applications require to be frequently changed, which has often a most beneficial effect on the ulceration.

With the view of correcting the fetor arising during the process of separation of mortified parts, charcoal has been employed. The common charcoal poultice is made by adding to a common bread and water or lintseed poultice, two ounces of finely levigated charcoal: this application generally destroys the fetor arising from the mortified parts.

The disinfecting agents which have been lately introduced—the chloride of lime, or of soda—when applied in proper strength to a gangrenous sore, remove very effectually the unpleasant smell, and may, therefore, be employed in conjunction with the other local measures. We distrust, however, the accounts given by the French writers of their power in

arresting the progress of mortification; in our opinion, they are useful only in correcting the fetor, and cleansing a foul sore.

When an extremity has become mortified, it is necessary to remove it to save the patient's life. The general rule adopted by surgeons is, to defer amputation until there is decided evidence that the mortification has stopped; but for information on this important point, we beg to refer to the writings of those surgeons who have discussed this point of practice.

It is necessary to advert to the treatment of mortification arising from unequal pressure on those parts on which the body rests, when an individual has been long confined to bed. The parts which are most liable to mortification from this cause are thinly covered with flesh, viz., the sacrum, hips, scapulæ, elbows, and sometimes the cartilage of the ears, and the skin covering the cranium. It takes place more especially in diseases attended with debility, as in the advanced stage of continued fever, in the typhoid forms of which there appears to be a tendency to gangrenous inflammation; it occurs also in bad compound fractures, in cases of tedious suppuration, and in paralysis; it is much favoured also when the evacuations are passed involuntarily.

According to Dr. Thomson there are two forms of disease arising from pressure, which are not always accurately distinguished; the one is mortification; the other a chafed, excoriated, and ulcerated state of the same parts; the mortified state, however, being always an indication of a greater degree of weakness. They not unfrequently occur in the same diseased surface, a part in which a mortified slough or eschar has been formed, passing very readily into ulceration, so that a sore, which at first was small, often acquires in this way a very large size.

The treatment depends on the circumstances with which each case is accompanied. When mortification occurs from pressure in the low or typhoid forms of fever, the strength must, as a general rule, be supported, unless special symptoms arise to render the tonic plan inexpedient. It is important, however, to discriminate the irritative fever which the mortification frequently induces, after the primary febrile symptoms have nearly or entirely disappeared.

When ulcerative or gangrenous inflammation arises in diseases in which the system is less disposed to mortification from failure of the vital powers, as in paralysis, bad compound fractures, and long-continued suppurations, there is less necessity for stimulants; mild nourishment, great attention to cleanliness, and suitable local applications, with attention to relieving the unequal pressure, forming the best plan of treatment.

For the purpose of obviating the unequal pressure sustained by those parts on which the body rests, various contrivances have been invented. A soft down pillow, or an air-cushion, may afford temporary relief. The bed invented by Mr. Earle is well adapted for many surgical diseases which require for their cure long confinement in one posture. The frequent failures of these various contrivances, however,

led our scientific friend Dr. Arnott to construct a *hydrostatic* or *floating* bed for invalids, on the following ingenious principle—that the support of water to a floating body is so uniformly diffused, that every thousandth of an inch of the inferior surface has, as it were, its own separate liquid, so that no one part bears the load of its neighbour; that a person resting in a bath is nearly thus supported; and that, though the pressure of the atmosphere on our bodies is fifteen pounds per square inch of its surface, yet because it is uniformly diffused, it is not felt. He also reflected that the pressure of a water-bath of depth to cover the body is less than half a pound per inch, even on the under side, where it is greatest, and similarly unperceived; and therefore concluded, that if a patient were laid upon the surface of a bath, over which a large sheet of India-rubber cloth (which is quite impermeable to water,) is thrown, the body being rendered sufficiently buoyant by a mattress placed under it, the invalid would repose on the face of the water without sensible pressure on any part, and almost as if the weight of the body were annihilated.

A bed constructed on this principle and made in the following manner has been found to effect this desirable object. A trough of convenient dimensions (six feet long, thirty-two inches wide, and eleven inches deep, are good common dimensions) is to be lined with lead or zinc to make it water-tight; this trough is to be half filled with water, and over it is to be thrown a sheet of the India-rubber cloth as large as will be a complete lining to it if empty. The edges of this sheet are to be touched with spirit-varnish, to prevent the water creeping round by capillary attraction, and to be afterwards secured, in a water-tight manner, all round to the upper border or top of the trough, the only entrance left being through an opening at one corner, which can be perfectly closed. Upon this dry sheet a suitable mattress is to be laid, and a bed is thus constituted ready to receive its pillow and bed-clothes, and cannot be distinguished from a common bed but by its surpassing softness or yielding.

When an invalid is placed on this bed, the body, being (as is known to swimmers) nearly of the specific gravity of water, displaces water equal to his own body, in weight as well as in bulk, and is supported as the displaced water would have been. If a mattress of a certain thickness be placed under the body, after the weight of the body has forced two cubical feet (the average bulk of the human body) of that under the level of the water around, he will float with four-fifths of his body above the level, and will sink much less into his floating mattress, than in an ordinary feather-bed. If unusual positions be required, by having the mattress formed of different thickness in different parts, or by placing a compress of folded blanket or of pillow under the mattress in certain situations, any desired position of the body will be easily obtained.

The hydrostatic bed does not admit of the perspiration being carried off, and unless the invalid can leave the bed so as to admit of its being aired daily, like an ordinary bed, it is

necessary to adopt a plan of ventilation in order to prevent the perspiration from being condensed on the water-sheet below. This Dr. Arnott has proposed to effect by placing under the mattress, arranged like the bars of a gridiron, small flexible tubes of copper wire, wound spirally, with their ends open to the atmosphere, either directly or through two larger tubes, crossing and connecting their extremities near the ends of the mattress, and then issuing at the corners of the bed from under the clothes.

This bed is therefore admirably adapted not only to every disease requiring long confinement to bed, but to cases of fractured bones, palsy, and diseases of the hip and spine. It also allows the patient, when capable only of feeble efforts, to change his position almost like a person swimming, and thus even to take a degree of exercise. It also enables the attendant to dress wounds, apply poultices, or to place vessels under any part of the body, as the elastic mattress may at any part be pushed down, so as to leave a vacant space, without the support being lessened for the other parts.

With regard to local applications, when the skin is merely inflamed without excoriation or detachment of the cuticle, the part should be frequently bathed with camphorated spirits of wine, or a solution of the acetate of zinc, or with a liniment made by triturating equal parts of alcohol and the white of an egg, and afterwards covered with soap cerate spread upon leather. When the skin is excoriated, spirituous applications are improper, the mildest emollients—the lin. calcis, simple cerate, or the zinc ointment—are suitable, and, if there be much irritation, an emollient poultice may be placed over the dressing.

When mortification, terminating in sphacelus, has taken place, a bread-and-water or carrot poultice is the best application, and if the separation of the sphacelus proceeds too slowly, a stimulant dressing, such as the resinous and turpentine before mentioned, may be applied for a short time, but it must be removed if it produce pain and irritation.

When the sphacelus has been completely detached, the sore is to be treated as a simple ulcer, the dressings being varied according to the state of the ulcerations.*

(Adair Crawford.)

(A. Tweedie.)

INFLUENZA. (*Epidemic catarrh.*) The disease now commonly known by this name, first given to it by the Italians, was not particularly noticed by physicians before the sixteenth century. Since that period it has many times appeared in Europe and in other quarters of the globe. Influenza seems to bear the same relation to ordinary catarrh that epidemic

cholera bears to the common or sporadic cholera that occurs every year. Of all epidemic diseases it is the most universal; and the rapidity of its march and extent of its range over land and sea, sometimes in both hemispheres and in different climates, in opposite seasons and in all varieties of weather, among people of all classes, naturally led to the supposition that some extraordinary influence could alone give rise to such a wide-spreading malady. The French call it *la grippe*, under which name Sauvages first described the epidemic catarrhal fever of the year 1743.

To collate the various accounts of any one visitation of this epidemic, such, for example, as that of 1775, or of 1782, or of 1803, in order to deduce some general principles respecting its mode of propagation, pathology, or treatment, would occupy a considerable treatise: it must, therefore, be an elaborate task to draw general conclusions from all the records we now possess of this singular disease, and to condense them in a space suitable for a work like the present. Limited by this circumstance, we shall take a brief survey, first, of the most remarkable dates of its appearance and progress in the last three centuries; secondly, its symptomatology; thirdly, its treatment; fourthly, facts and general inferences relative to the causes of it, such as phenomena of the weather and diseases among brutes; fifthly, its contagious property; and, sixthly, its influence on other diseases, and connexion with diarrhoea, dysentery, and cholera.

I. We find no medical description of the epidemic catarrhal fever before the year 1510. "It was called *cocoluche*, because the sick wore a cap close over their heads." The symptoms of the disease, as it then occurred, nearly resembled those which it has assumed in later visitations, namely, severe pain over the eyes, sneezing, coryza, heaviness, difficulty of breathing, hoarseness, loss of strength and appetite, fever and harassing cough. Schenk says that physicians then looked upon it as a new disease. Its course seems to have been in a north-westerly direction, from Malta to Sicily, Spain, Italy, Germany, France, and Britain; and Short says that "it attacked *at once*, and raged over all Europe, not missing a family, and scarce a person, and that none died except some children. In some it went off with a looseness; in others by sweating. *Bleeding and purging did hurt.*"*

In 1557, an epidemic of the same nature prevailed in different countries. Fonseca says that in this year it infested Asia, thence came to Constantinople, and having spread itself all over Europe, afterwards attacked America, its course being westerly. Mercatus asserts that "before the beginning of autumn 1557, it attacked all parts of Spain *at once*, so that the greatest part of the population in that kingdom were seized with it almost on the same day."†

* We omitted to state, in describing one of Kaltenbrunner's experiments, p. 720, that, after repeating these experiments, we have not been able to distinguish the ulcers alluded to, though this author affirms that he has distinctly observed them with the microscope.

‡ The portion of this article which precedes the initials A. C. is written by Dr. Crawford, and the succeeding portion by Dr. Tweedie.

† See Report, by Dr. Glass, in Lettson's Memoir of Dr. Fothergill, 4to, p. 625.

Riverius has transmitted to us an account of this epidemic. Unlike that of 1510, it was fatal to many: in a small town near Madrid, Mantua Carpentaria, bleeding was said to be so fatal that two thousand patients died after it in September.* At Alkmaer, in Holland, two hundred died of it in October.

The catarrhal epidemic fever of 1580 was distinguished by its complication with malignant fever or plague, as related by Forestus and Sennertus.† The latter speaks of its ravages at the end of summer and the beginning of autumn over all Europe; in some parts of which, as in Paris, it was the *precursor* of the plague.‡ It was in Sicily in June, at Rome in July, in August at Venice and Constantinople, in September in Hungary and Germany, in October on all the Baltic coast, in November in Norway, in December in Denmark, Sweden, Poland, and Russia; its course being from E. and S. to W. and N.§ Mercatus says that it raged also in Spain, and destroyed not a few.|| Grand Cairo lost a prodigious multitude the same year by the plague. It is a remarkable fact, and ought not to escape our notice, that France appears to have been the only country in Europe affected that year by the plague; and it appears also to have been the first to be visited by the epidemic catarrh, its precursor; so that Baldutius even dates its origin from France.¶

The influenza of 1658, of which Willis has left us an account, visited Europe and this kingdom *suddenly* in April, and after excessive heat in August was followed by a fatal epidemic fever.**

Sydenham and Etmuller have described the epidemic catarrh of 1675, which began in Germany in September, and in England in October. Malta was afflicted by the plague the same year, from which it remained free till the last severe visitation of this scourge in 1813.

The epidemic catarrhal fever which raged during the autumn and winter of 1729, in the space of five months' time visiting almost every part of Europe, was very fatal in many large cities, such as Paris and London. Loew says that in the latter more persons died than at any one time since the plague of 1665, about one thousand being cut off weekly in September. In the beginning of winter it reached France. A few weeks after, it visited the upper part of Italy with great mortality. In February it afflicted Rome and the Rhine. Turin and Milan suffered extremely. It reached Naples in March, and after this disappeared.††

The influenza of 1732-3 is described in the second volume of the Edinburgh Medical Essays, and by Huxham; and was so far remarkable that it affected the mucous membrane of the alimentary canal as well as that of the organs of respiration. It spread over all

Europe, and appeared also in America. It was first noticed about the middle of November in different parts of Germany. Edinburgh appears to have been the first place attacked in Britain, viz. on the 17th of December, and it raged at the same time in Switzerland, at Basle. It appeared at London and in Flanders the first week in January; towards the middle of the same month it reached Paris, and Ireland towards the end. Cornwall and Devonshire were visited about the beginning of February; few only were attacked at Plymouth, where Huxham practised, so soon as this; but in March it prevailed on all sides. In February Leghorn was attacked, and near the end of it Naples and Madrid suffered. New England in America was invaded by the distemper about the middle of October, which travelled southward to Barbadoes, Jamaica, Mexico, and Peru, much at the same rate as it had done in Europe. It appears to have been at Paris early in the year. "Elle se manifesta, dit de Jussieu, à la suite de brouillards fétides, plus épais que les ténèbres de l'Égypte."**

The epidemic catarrh of 1733 was followed by those of 1741 and 1742; the first described by Haller, and the second by Sauvages and Huxham. In 1743, towards the end of April, Huxham says that it was general in England, and in the spring spread over all Europe under the name of "influenza," or "grippe." This epidemic was the *precursor* of the plague of Messina in Sicily the same year; and it was more fatal in the southern parts of Europe than in England, though it increased the deaths in London in one week to a thousand.†

The next remarkable visitation of the influenza was in 1762; and an elegant description of it is given by Sir George Baker, "De Catarrho Epidemico anni 1762," who records its appearance in London about the 4th of April. Razoux, a physician of Nismes, has given an account of the same disease, which was epidemic in Europe generally in the spring.‡ It attacked Breslau at the end of February; Vienna was visited in March, and Hamburg in April. In Venice it was more fatal than in other places. It spared, however, Paris and the greatest part of France; nor can we find any particular cause for this exemption. Nismes most probably was visited; and Webster says that "Toulon lost one-third of its inhabitants by an epidemic in 1761." The influenza of 1762 appeared sooner in London than in any other part of England, namely, the beginning of April. It was not observed in Edinburgh and Dublin till May; but in June it was general and severe, according to Sir G. Baker, being seen no where earlier than February nor later than July. It had prevailed in America the preceding year.§ It was not till July that it attacked the British sailors in the Mediterranean. It was immediately followed in London by an epidemic dysentery, which raged till November. While the influenza prevailed,

§ Webster's Hist. i. p. 410.

the deaths in London scarcely exceeded the usual number. In Manchester they were even fewer than common; and at Norwich far more died of it than fell victims to the *more severe* influenza of 1743.*

The next epidemic catarrh, in order of time, was that noticed in London and different parts of the nation by Dr. Fothergill and some of his friends in the latter end of the year 1775. It was observed also in France, Holland, and Germany, and was supposed to be more fatal in those countries than in Britain.†

The influenza of 1782 was general over England, Scotland, and Ireland, between the months of May and July inclusive. A full account of it is given in the second volume of *Memoirs of the London Medical Society*, by Dr. R. Hamilton, which is the groundwork of the article "Influenza" in the *Edinburgh Medical and Surgical Dictionary*; an account is also given in the first volume of *Medical Communications* by Dr. Gray, compiled from papers in the British Museum, which is the basis of a like article in the *Cyclopædia* of Dr. Rees. (See also the third volume of *Transactions of the College of Physicians*, London.)

The influenza of 1782 seems to have pursued a course from the east, not very different from that of the epidemic cholera which is now (1832) displaying its ravages in Great Britain and France. It is reported to have broken out in September 1780, and to have become very general in the crew of the *Atlas* East Indiaman, whilst that ship was sailing from Malacca to Canton. When the ship left Malacca, there was no epidemic disease in the place; when it arrived at Canton, it was found that at the very time when they had the influenza on board the *Atlas* in the China seas, it had raged at Canton with as much violence as it did in London in June 1782, and with the very same symptoms. In October and November 1781 it appeared in the East Indies, and was said to have attacked the British army while it was besieging Negapatam in November 1781. Its progress is stated by Webster to have been from Siberia and Tartary westward. At Moscow it prevailed in December 1781; at Petersburg in February 1782; and it was traced to Tobolski. It was in Denmark in the latter end of April. From the shores of the Baltic it spread to Holland and the Low Countries, and thence to England. London was said to be attacked sooner than the west and north; Ireland a few weeks later, and the south of Europe later still; for it prevailed in France in the months of June and July, in Italy in July and August, and in Portugal and Spain in August and September; seldom continuing longer than six weeks in any place.‡

The influenza of the spring of 1803 afforded

an occasion for collecting a great number of notices from different parts of the country on the subject of this epidemic. The London Medical Society set a laudable example by proposing a set of queries to its corresponding members in a circular letter; and the sixth volume of "*Memoirs*" contains reports from nearly sixty practitioners in England, Scotland, and Ireland, as to the date of its first appearance, its symptoms, treatment, &c. in their respective neighbourhoods. Dr. Beddoes also interested himself very zealously on the same occasion, and procured various testimonies from his friends and others, which, to the number of one hundred and twenty-four, are inserted in the ninth and tenth volumes of the "*London Medical and Physical Journal*." These documents contain a mass of very useful information. This epidemic was observed at Paris and in other parts of France and in Holland some weeks before it appeared in London; and Dr. Bardsley says "the same length of time was occupied in its progress from the latter city to Manchester."§ Its course seemed to be from S. to N. It was in Cork and Dublin before it reached the north of Ireland, immediately after a S.E. wind. An epidemic ophthalmia followed it in France,† and a severe dysentery, such as had not been known for thirty years, in some parts of the United States, which it visited the same spring.‡ It was observed to be epidemic in Sussex, and some of the counties in the S.W. as early as February; in Shropshire, Nottinghamshire, &c. in March; in Yorkshire and Lancashire in April; and at Sunderland in May.§ It was evident that there was a degree of progressive movement northward, by marking the time when it was at the height in each place; yet many of the accounts above alluded to inform us clearly that sporadic or solitary cases exhibiting the true characters of influenza, occurred in several places long before the disease became established, so as to manifest a universal tendency to that form of complaints over the country, in some cases weeks before it was quite developed. It is worthy of notice that this has been remarkably the case with the epidemic cholera. Dr. Gray observes that, in 1782, a complaint, similar to the influenza, was taken notice of in some parts of the kingdom several months before that disorder made its progress through it.||

The influenza of last year (1831), though generally mild in its character, was almost universal; for it would seem to have prevailed in both hemispheres in the same year. Accounts have been received of its appearance in India as well as in the United States of America.¶ In many places it has been the precursor of the epidemic cholera. About a month before the latter disease broke out in Warsaw, it pre-

vailed in that city.* It also swept over great part of England, Scotland, and Ireland, in the spring and autumn, and preceded the *milder* visitation of epidemic cholera which many parts of Great Britain experienced the same year. Late in the autumn it attacked Paris, the south of Spain, Gibraltar, and Italy, with more severity than it did the British islands. At Rome it was said to occasion great alarm. It has certainly skipped over many countries of Europe in its march from Poland to France through England, so far as we can judge negatively from the want of official reports; but, with this exception, it has pursued a course not widely different from that of similar former epidemics, and has proved to be a true herald of the epidemic cholera in many places.

II. The influenza does not seem to have exhibited a greater variety of symptoms, in its different visitations, than other epidemics. It has varied a little in town and country, in spring and autumn, at the beginning and end of the epidemic, in different persons, and according to the particular *genius* or tendency of the epidemic constitution; but still it has maintained some prominent characteristics of its identity at different periods. The ordinary course of the disease has been marked by the following symptoms:—it usually commenced with slight chills, amounting sometimes to shiverings, and alternate flushings of heat, with languor and sense of extreme weariness; then, soreness over the eyes, or pain in the course of the frontal sinuses: these were quickly followed by frequent sneezing, a copious discharge of lymph or thin clear fluid from the nose and eyes, sometimes so acrid as to excoriate the upper lip; heat and soreness in the top of the larynx and œsophagus, and along the course of the windpipe, with hoarseness and dry cough; sense of stricture in the chest and difficulty of breathing, sometimes attended with darting pain in the muscles subservient to respiration; weight and anxiety about the præcordia, flying pains in the back, knees, calves of the legs, and various parts of the body; depression of spirits, and sudden and extraordinary prostration of strength. The tongue was mostly covered, at an early period of the complaint, with extremely white mucus, like cream—a symptom particularly noticed by Huxham, Baker, Pettit, and others: there was loss of appetite, the thirst was inconsiderable, and the pulse generally quick, weak, and soft.

The preceding symptoms appeared in various degrees and combinations, as the violence of the disease fell more particularly upon the mucous membrane, in the head, in the throat and chest, or in the stomach and bowels. When the disease chiefly affected the head, vertigo, violent headach, greatly increased by the cough, and delirium, were not unfrequent: there was hemorrhage from the nose, and pain in the ears; from which, in one case, a clear fluid was poured out like that from the nostrils.†

In some rare cases the tonsils and back part of the throat were inflamed, so that suppuration was the consequence. When the violence of the disease fell upon the lungs, as in old people, asthmatic patients, and those predisposed to phthisis, hæmoptoe was not uncommon, and frequent troublesome cough which prevented sleep. It often degenerated into pleurisy and peripneumony. In common cases the cough became loose in three or four days. The stomach was affected with nausea in many, and vomiting in some; and a spontaneous diarrhœa relieved both head and lungs, and speedily cut short the complaint. But in many instances, and in several visitations of the epidemic catarrh, a morbid determination to the intestinal canal was manifest from the beginning; which, so far from being considered a salutary effort of nature to relieve the system in that way, required especial care in the treatment, and the utmost caution in the use of purgatives. The fever was generally mild in the day-time, and it increased in the evening; and it seldom abated till some critical amendment took place by perspiration or otherwise. There was little remarkable in the urinary secretion. The duration of the complaint was from a day or two to a week or fortnight. In some, the symptoms, after abating in two or three days, returned and raged with violence. The far greater part had critical sweats about the third day, which, attended with free expectoration, banished the fever on the fifth day. One of the most remarkable features of influenza is the debility; so that many could not rise from the horizontal posture without sudden faintings, even in the stage of convalescence; and the debility often remained for a considerable time. The suddenness of the invasion, the pain and tightness in the forehead, with pain in the back, knees, and muscles, and singular prostration of strength, were thought to be distinguishing marks between the influenza and common catarrh. Indeed, the pain or soreness in the face, temples, and cheek-bones, was considered the most certain pathognomonic symptom in 1782; “and now and then was felt previously to the catarrh, and not unfrequently was followed by very little or no catarrhal affection.”

In one district in Gloucestershire, a practitioner states that “in no two persons in 1803 did he observe precisely the same symptoms.”* If this was the case, the symptoms might be expected to vary considerably in different places, as well as in different visitations of the distemper. And this has happened accordingly. The rarer occurrences were, an unusual disposition to sleep, stranguy and bloody urine independent of blisters, *peculiar slow and strong pulse*, with excessive debility, as at Newark; ringing in the ears and abscess, and abscess in the frontal sinus; of which last Dr. Rush had three cases in 1790.†

The duration of influenza in any one place seldom has exceeded six weeks. Upon the whole few have died of this complaint, although it has often attacked more than one-half or even three-fourths of a whole community. The chief victims have been the aged and asthmatic, those of tender lungs and of full oppressed habits. Those of middle age were more liable to be affected than old persons and children; and persons exposed to the air than those who were confined. Many recovered their strength very slowly, and some, especially in 1762, fell into incurable consumption.

III. One general observation seems to apply to almost every epidemic disease, including even those of a pestilential nature, viz. that during its prevalence numbers are attacked in so slight a manner as to require but little medical care. Hence the influenza, which in all its visitations has had a favourable character in the majority of cases, has been easily removed by mild diluents, rest, and abstinence for a few days from animal food and fermented liquors. Besides this, a complaint so various not only in its symptoms but in the degrees of their intensity, modified too at different periods by season, climate, and epidemic constitution, would of necessity call for the exercise of much discretion in the employment of remedies. But, making due allowance for all this variety of character in the complaint, and for the judicious adaptation of a corresponding treatment, physicians of eminence, in different countries, seem to have agreed remarkably in their testimony as to the general rules and principles of their practice; and from the very beginning of the sixteenth century, in their reports, with respect to bloodletting, to the caution about active purgatives, to the employment of a cold regimen, and to the restricted use of opiates, there is a very striking and satisfactory coincidence.

In the mild attacks of the disorder, few if any medicines have been required. In severe cases, emetics at the beginning relieved the sufferings of the head and chest, and, combined with gentle aperients and antimonial or saline medicines, were found useful in mitigating the fever and promoting a salutary diaphoresis.

No observation is to be found more general in practical writers in this disease than that bloodletting could rarely be employed with safety, far less with benefit, on account of the alarming debility and weakness of the pulse; and when it was strongly indicated, practitioners were sparing in the quantity of blood, and cautious in repeating the remedy. In the epidemic of 1510, Dr. Short tells us that "bleeding and purging did harm." In 1557, bleeding was said to be so fatal, that in a small town near Madrid two thousand persons died after it in September. In 1580, Sennertus ascribes the death of two thousand persons in Rome to venesection, and states that, where it was omitted, the mortality was not greater than one in a thousand. "*Experientia enim hoc comprobavit, omnes fere mortuos esse, quibus vena aperiatur.*" Forestus, in his Scholia

on the same epidemic, suggests a good practical hint, that we ought to distinguish very carefully those cases which might require, from those which might not bear this remedy. Huxham, who had no prejudice against bloodletting, remarks, "*Imo, si vel peripneumoniae aliquid subsesset, minime largam, sine maxima virium ruina, plus vice simplici venesectionem tolerabat: nec in hac solum, sed in omni febre catarrhali epidemica hoc fere perpetuum notavi.*"* In Edinburgh it was noticed that those who were bled, in 1733 and 1782, "recover more slowly;" though others at the commencement seemed to be relieved by the lancet.† In the influenzas of 1733, 1775, and 1803, in France, bloodletting was generally injurious.‡ Dr. Glass reports that at Exeter, in 1775, venesection "weakened the patient without relieving the pain;" and Dr. Ash considered that "it was never necessary to bleed at Birmingham; that in a neighbouring town, three died who were bled, and all recovered who were not bled."§ Dr. Gray gives it as a general inference from the accounts transmitted to a "Society of Physicians" in 1782, "that bloodletting was by no means conducive to the general cure of the disease."|| Many physicians bear testimony to the same good rule of practice in the influenza of 1803, as Dr. Bardsley of Manchester, Dr. Kinglake of Taunton, Dr. Rutter of Liverpool, and others.¶ Notwithstanding the foregoing authorities, it is admitted by some eminent physicians, that cases now and then occurred in which this remedy was useful. Sir George Baker made this observation in 1762, in London (p. 29); and in the same city it is somewhat remarkable that in the epidemic of 1775 it was less hurtful than in other places, which was perhaps owing to the more frequent complication of the disease that year with pleurisy and peripneumony, at all times no unusual circumstance.

Opiates at the commencement of the disease almost invariably increased the febrile heat, aggravated the headach, in some cases even to delirium, tightened the chest, and stopped the expectoration; but in the decline they proved salutary. A cool temperature, both in drinks, in the air of rooms, and in the quantity of bed-clothes, was found to be useful; while, on the contrary, warm rooms, hot drinks, and cordial sudorifics, aggravated the violence of the disorder. Blisters to the chest, sides, or back, often greatly relieved the stitches and cough; and ipecacuanha was much extolled, especially in France, for its efficacy, when given in small doses, in assisting expectoration, relieving the oppressed lungs, and correcting the tendency to irritation of the mucous membrane of the bowels. A medicine often used with good effect to ease the cough when attended with viscid phlegm, was the solution of gum ammoniac combined with oxymel of squills.

When recovery was tedious and the strength much impaired, even long before the cough was removed, some bitter infusion, such as that of calumba, cascarilla, or Peruvian bark, with wine-why and some nutritious diet, was of great service. The reason why purgatives have been so generally reprobated by practitioners in the influenza, appears to have depended on the fact, that a morbid state of the mucous tissue of the internal surfaces exposed to the air, was often closely connected with a morbid tendency in that of the alimentary canal; and, therefore, drastic purgatives, though they might relieve one system or set of organs, yet too often only transferred the disease, as it were, to another, and produced a dangerous debility.

IV. Amongst the phenomena relating to the weather, which seem to have had a connection with epidemic catarrh, either as precursor or attendant signs, we may notice extraordinary vicissitudes, easterly winds, thick or offensive fogs, and diseases, often of a similar kind, among horses, dogs, and cattle. Epidemic catarrh is a disease either of spring or autumn. The spring influenzas have sometimes occurred when the first heat suddenly followed the winter's cold; and the autumnal, when the cold moisture and raw fogs of November have succeeded to the heat of a dry harvest; yet there has not been a uniform connection between any one sensible quality of the atmosphere as to heat or cold, rain or drought, wind or calm, and the prevalence of this epidemic; for in different places it has maintained itself under the dominion of each of these states of the weather, "et tempori frigidiori et calidiori, et flante tam austro quam Borea, et pluvioso et sereno cœlo, peragravit hasce omnes Europæ regiones, et omnia loca indiscriminativim."* In fact, extraordinary vicissitudes have been more remarkable than any thing else: in some places, one peculiar sign of atmospheric intemperature has been observed, and in other places a different sign; and the epidemic has frequently fallen capriciously or partially, like the blight over a country, or even over a garden.

Short says that "thick, ill-smelling fogs preceded, some days, the epidemic catarrh of 1557. July, August, and September had been very hot and dry; and in the end of September came a very strong cold north wind."†

Riverius, quoted by Saillant in his History of Catarrhal Epidemics, says that just before that of 1580 appeared in France, (at Nismes or Montpellier?) "a prodigious quantity of insects appeared in April and May; and the roads were covered with them in such a manner, that a person in walking might have destroyed them by thousands."‡ And Petrus Salius Diversus, cited by Dunning, tells us of the birds and brute animals suffering generally

the same year.* To these facts we may add the observation of Short, that "after a long continuance of hot, moist weather, attended with southerly winds, at the rising of the dog-star came a cold, dry, north wind; and from the middle of August to the end of September raged the malignant epidemic catarrh."† Great extremes of the weather preceded the epidemic catarrh of spring 1658, described by Willis;‡ and Sydenham attests that "the epidemic catarrh of autumn 1675 immediately succeeded cold and moist weather, which suddenly followed an unusually warm summer."§

We have no very particular account of the state of the weather in England attending the epidemic catarrh of autumn 1729; but Hoffmann does not hesitate to ascribe its origin in Germany to the uncommon "irregularity and frequent changes of the weather from heat to cold and from cold to heat, &c. which distinguished that and the preceding year, such as he had never before witnessed; causing throughout all Germany, Belgium, England, and elsewhere, unusual sickliness: "tam uberi proventus enati fuerint morbi, quam vix alio tempore visum unquam."||

Within the last century the number of observations on the phenomena in question increases very considerably; and we are thus enabled to make some approximation to general principles. Saillant's excellent work,¶ on the continent, and the facts which have been collected in this country, on the catarrhal epidemics of 1775, 1782, and 1803, afford us much assistance in this inquiry.

De Jussieu says that "the influenza of spring 1733 appeared in France immediately after offensive fogs, *more dense than the darkness of Egypt*," (plus épais que les ténèbres de l'Égypte.***) Huxham remarks generally that the cause of epidemic catarrh seems to depend on a thick, moist, and cold air; and that in the autumnal months preceding the spring catarrh of 1733, epidemic diseases were very common and fatal among horses.†† We find, also, that about Edinburgh coughs and running from the nose in horses were universal in October and November, just before the disease attacked men.‡‡

The influenza of spring 1743 was the precursor of the great plague in some parts of Sicily. In England it was not so severe and fatal as in some other parts. About Plymouth, according to Huxham, many horses were diseased, and deer perished in January.§§

Sir G. Baker says that the weather in spring 1762, before the epidemic catarrh of that year

broke out in London, was extremely irregular; wind, frost, snow, and rain following each other in rapid succession, and with unusual severity. In April and May intense heat followed; and besides this, the air underwent very sudden changes from heat to cold and from cold to heat.*

A hot dry spring and summer preceded the epidemic catarrh of autumn 1775. Petit says that in France the disease was ushered in by thick noisome fogs ("brouillards fétides"), and a cold rainy autumn.† Dr. Anthony Fothergill says that disease among dogs and horses was general over England before the influenza broke out;‡ and we are also assured that it was preceded by foggy air as well as by disease among dogs and horses in Dorsetshire, and at Exeter; and by unusual haze, easterly winds, and almost universal cough among the horses in North Wales.§ About the 7th of October, 1775, it appeared in the shire of Galloway in Scotland; "and a continual dark fog and particular smoky smell in the atmosphere prevailed for five weeks, the sun was seldom seen, and though October and November are particularly rainy months in that country, little or no rain fell, the wind E.S.E. and S."||

With regard to the influenza of spring 1782, "the spring of this year was remarkably late, with a long prevalence of cold easterly winds; the hedges were not full blown in Cornwall before the beginning of June. A similar state of weather has commonly ushered in this universal malady."¶ Dr. Hamilton tells us that "from the first of January till the end of May, throughout most places in the kingdom, the weather was uncommonly unfavourable;" and it appears that the latter month "was remarkable in all the meteorological annals of Europe for its unusual degree of cold and humidity, with a gloomy and uncommonly disturbed state of the atmosphere."*** Dr. Darwin adds his testimony, that in this year (1782) "the sun was for many weeks obscured by a dry fog, and appeared red as through a common mist;" and he supposes, "the material which thus rendered the air muddy, probably caused the epidemic catarrh which prevailed in that year."†† Dr. Parr says that horses were affected with a cold at the same time, near Exeter.‡‡ Maertens records a striking fact relative to the first appearance of this epidemic at Petersburg, and its connection with a particular change of the weather: "On a cold night the thermometer rose 30° of Fahrenheit; the next morning forty thousand people were taken ill with the influenza."§§

The influenza of spring 1803, as we have

said, afforded an occasion for the collection of many valuable observations. It appeared in France some weeks before it invaded this country, and was supposed to be owing to a cold and humid autumn succeeding a dry and hot summer. At Paris it was immediately followed by a severe epidemic ophthalmia, about the time the influenza first appeared in Britain.* With respect to unusual extremes in the weather, such are stated to have occurred in Hampshire, London, Somersetshire, and St. Andrews in Scotland.† "I am of opinion," says Cuming, (Romsey, Hants,) "that the remote causes of this disease originated in the sudden change of atmosphere, a change, I believe, generally felt throughout the United Kingdoms, as well as upon the continent." Epizootic diseases preceded it, in some places among one or two species of animals only, in others among several, as cats, dogs, horses, cows, sheep, swine, in Shropshire, Worcestershire, Staffordshire, Cumberland, Hampshire, Lancashire, &c.‡ At Plymouth "many attributed the disorders among the horses to their having eaten insects, which for many weeks were innumerable, and covered the fields in a most extraordinary manner wherever there was any length of grass; and this, from the mildness of the season, was general in almost every field."§

Disease was very prevalent among sheep in some parts of the north of England, last spring (1831), just before the influenza appeared; and an epidemic catarrh seems to have raged among horses in the south later in the year. The influenza of this year was remarkable for this, that it prevailed in some parts of Great Britain in spring, and in other parts in autumn. Its character was generally mild in all. With regard to the weather, an intelligent captain of a regular trader in the English channel declared to the writer of this article, that for thirty years past he had no recollection of such a long continuance of a thick and foggy atmosphere, as he has had occasion to observe within the last eighteen months, between this country and the south of Ireland. He went so far as to state that he had scarcely made one clear passage from Liverpool and back again during this whole period.

One general inference offers itself to our notice on reviewing the foregoing facts, viz. that no particular phenomenon in nature universally characterizes the epidemic constitution which precedes, or that which accompanies the disease called influenza; and we are led to conclude that the causes of this epidemic, supposing them to take their rise in atmospheric changes of a universal nature, are far from being marked by uniformity in the signs. At the same time we are bound to admit that the changes from warm weather to cold, and

from cold weather to warm, with dampness, fogs, and easterly winds, have rarely been absent from the catalogue of natural indications. Disease among domestic animals is also to be noted as a very common precursor in many places, and in several distinct visitations of the influenza.

V. The influenza, like every other epidemic disease, has given occasion to medical observers to entertain very opposite views on the question of its contagious property. Were we to draw a general inference from the recorded statements of the majority, we should say that it was *not* contagious; for the numbers who have given an opinion on this side far exceed the advocates of contagion. But we must not appeal to the majority in order to decide a principle in science. It must, however, be acknowledged, that while individual or partial occurrences might lead to the supposition that influenza was propagated in many instances by contagious transmission, a comprehensive survey of facts goes far to establish the contrary opinion; for some things can hardly be explained on the principle of contagion without having recourse to suppositions that could not be warranted by a sound induction. Upon the whole it would appear that some general cause, if not originating, at least subsisting in the atmosphere, and depending on its changes, progressive also in its movements from place to place and from country to country, gives rise to the disease; but that it is probable that a limited propagation *also* takes place by personal intercourse, *under the influence, and during the prevalence, of the epidemic constitution.*

We have writers affirming that persons who have been visiting or on business in an *infected* town, have been the first to introduce the epidemic into their own town or neighbourhood; and it cannot be doubted that the members of a family and the inhabitants of a district have often been attacked by the influenza in *succession*. Hence these things would seem to indicate that the disease was propagated by contagious transmission more than by some universal medium. But the difficulty of proving the first to be actually the case, must, in the nature of things, be very considerable; for it would appear,—and the remark applies to almost every epidemic disease,—that in many places a tendency to the epidemic has been recognized by clear indications some time *before* the peculiar combination of symptoms which characterize it have shewn themselves, making the moment of actual invasion very doubtful; just as, it is well known, the epidemic imprints its own character for some time *after* upon the diseases that follow it. And though no *epidemic* disease with which we are acquainted is so sudden and simultaneous in its attacks as influenza, and therefore none more emphatically deserves the name of *epidemic*, nor more decidedly proves a universal cause; yet it is a striking fact that, with all its frequent rapidity of movement over the globe, it has in almost every country been more or less obedient to the laws which govern other epidemics, according to some *progressive* and *consecutive* operations that are as much

hidden as the efficient cause of attraction. It does, in fact, mostly observe some progressive law in moving over a country and in attacking a given multitude of people, which demonstrates that, however universal may be the cause of an epidemic disease in its purest form, yet if we regard experience, the effects rarely if ever should be expected to appear without some degree of consecutive order. The difference of constitution, of age, of habits, of locality, and of other things, may be quite sufficient to account for the phenomenon of successive attack; and, indeed, it is what we might expect a priori. If to this we add the probability, and, indeed, necessary inference from the facts, that the cause itself is developed gradually, we shall have less difficulty in accounting for a continuous mode of attack on another principle than that of contagion.

Though a successive mode of propagation over a country or city is most usual, yet on some occasions the spread of influenza over a whole kingdom, within the space of a few days, has been so general as to make the propagation by means of personal intercourse quite incredible, and almost impossible. Besides this, its sudden appearance in ships at sea, which have had no intercourse with land or with other vessels for a considerable time, can hardly be explained on any other supposition than that of its atmospherical origin. Dr. Anthony Fothergill assures us that “both the epidemics of 1758 and 1775 seized whole families on the same day, often remote from one another, and without any intercourse.”* Again, “the influenzas of 1775 and 1782 seized some persons at sea, while others were attacked on shore, and that without any perceptible communication.”† “The appearance of the influenza in 1803 in England,” according to Dr. Woodforde, “was very sudden, and its attack extremely general, so that it is difficult to say in what or in how many parts of the kingdom it prevailed at first. It is probable that the disease broke out in all at or nearly the same time.”‡

The following fact is very conclusive as to the operation of some general cause; for it is scarcely probable that contagion could be lurking a long time before, and then should burst forth at the same time at distant points in so remarkable a manner. Two separate fleets left the coast of England for different points of destination in the year 1782; one, under Admiral Kempenfeldt, on the 2d of May, to cruise between Brest and the Lizard; the other, under Lord Howe, on the 6th of the same month, for the Dutch coast: neither fleet had communication with any shore; and the crew of each was perfectly healthy on sailing from Spithead. But on the 29th of the month, near four weeks after, the crew of the *Goliath*, one of the ships under Kempenfeldt, was attacked with influenza, and about the same time the epidemic appeared also in the *Rippon*, under Lord Howe. The other ships of both fleets were attacked in suc-

‡ Med. and Phys. Journ. vol. ix. p. 505.

cession. In fact, so many men of both squadrons, on these remote stations, were rendered incapable of duty, that all were obliged to return to Portsmouth about the second week in June.*

If we pay attention to the course or direction of the several visitations of the influenza, we may observe that its general progress is not without some order. It either follows a westerly course, or one from the south towards the north. If its course be westward, it does not usually take extensive leaps over kingdoms, and then return to those it may have missed, as would be likely to happen if nothing more than personal intercourse and the various casualties of travellers' routes exerted an influence in determining its course. But it sweeps along the north from the east through Russia, Poland, and the north of Germany to England; and then wheels round through France and Spain to Italy. And here we cannot but trace a striking resemblance to the career of the epidemic cholera. But if influenza arises in the south, it takes a course from Italy through Spain, France, Britain, and the Netherlands, along the shores of the Baltic. In the one case France is attacked before England, in the other after it.

Were we to admit that the propagation of an epidemic disease over a space of some hundred square miles in the course of a few days or weeks might be accounted for on the doctrine of contagious transmission by means of travellers and the facilities of human intercourse, analogy might supply us with an argument against the admission; for in the case of some of the domestic animals, which do not travel from country to country like man, but are comparatively stationary, epidemic diseases are observed to spread among them, sometimes in as extensive and simultaneous a manner as amongst human beings.

VI. The facts we are now to notice seem to afford strong indications of the influence which the general cause that produces epidemic catarrh exerts over the human body with regard to other diseases; and so far they are opposed to the theory that contagion is the cause of it. Webster has remarked that catarrh or influenza is the disease which is most clearly connected with pestilence in the form of malignant angina, dysentery, yellow fever, and plague, which it usually precedes.† This observation is partly confirmed by subsequent experience. These facts also show how the general cause is controlled or modified by local peculiarities, as well as by constitutional varieties.

Sir George Baker tells us, that "while the influenza of 1762 was prevailing in a very mild and tractable form in the villages near Lincoln, that were high and exposed, quinsies, pleurisies, and peripneumonies produced incredible destruction of life in the low neighbouring districts.‡"

Dr. Carrick of Bristol says that "one of the most open and exposed of the buildings on Clifton Hill is Richmond Terrace, which forms three sides of a parallelogram, fronting respectively the east, south, and west. On the east side, not one family, scarcely an individual, escaped the complaint (in 1803), while on the south side a great majority both of persons and families, in all other respects similarly circumstanced, escaped it entirely."*

Dr. Binns states that at the time the scarlatina existed at Ackworth School in 1803, the influenza prevailed in the neighbouring towns; yet that the latter did not attack a single individual of the family at the school, consisting of between three and four hundred persons.† Burton-on-Trent, also, in great measure escaped the influenza the same year; and scarlatina, with whooping-cough and measles, were epidemic there in its place.‡

"In London the influenza of 1803 superseded or deferred the usual diseases of the spring, as the measles and scarlatina; this is also recorded by Lorry to have been the case in the epidemic catarrh that prevailed in France in 1775; but he adds, that during the summer these complaints appeared with more than usual violence and fatality."§

"At Aberdeen the influenza of 1775 began near the end of November, and continued four or five weeks, but did not visit Fraserburg, where there was a putrid fever very fatal at that time."|| At Chester, according to Dr. Haygarth, "the same epidemic, in 1775, attacked many who were confined to their houses and even to their beds with other ailments."¶

Dr. Vaughan says that at Rochester, when the influenza of 1803 ceased, "an exanthematous fever prevailed, which did not appear to attack any except those whom the influenza spared."***

Dr. Gibney reports that "at Navan in Ireland, after the influenza of 1803, a low fever, almost constantly prevailing in that town, disappeared for a considerable time."††

Dr. Currie states that "at Holywell, a populous town eighteen miles from Chester, and where there is a large cotton manufactory, a typhous fever of uncommon malignity had prevailed for a considerable time: the manufacturers and inhabitants of the town had not been free from it for more than two years. On the appearance of the influenza in the spring of 1803, the typhus entirely ceased, and only one case of fever has occurred since (nearly three months). I have not for many years known this country so healthy as since the influenza disappeared."‡‡

Dr. Rush remarks that, during the prevalence of the influenza at Philadelphia, he saw no

sign of any other epidemic, and that the scarlatina anginosa, which prevailed during the summer, disappeared after the 1st of October, but appeared again after the influenza left the city. It blended itself with every species of chronic complaint.”*

“The influenza was the precursor of the malignant yellow fever, which, commencing in the beginning of September, 1802, at Fort Royal and St. Pierre’s, Martinique, among the French seamen and soldiers lately arrived from France, committed the most frightful devastations amongst them.”†

“During the prevalence of influenza at Vienna, from December 1788 to May following, there were scarcely any instances of real pleurisies or peripneumonies, though these often appeared during that season in former years.”‡

Dr. Chisholm mentions the exemption from the severe influenza of 1789 in its malignant form, after a remarkable change in the weather, of some estates in the island of Grenada, which had been attacked by it in its milder character before the change took place.§

While the influenza of 1762 was in London, peripneumony and angina were unusually and almost universally prevalent in the country;|| and Dr. Carmichael Smyth relates, that “although the epidemical catarrh of 1782 quickly disappeared in the metropolis, it seemed to leave behind it an epidemical constitution which prevailed during the rest of the summer: and the fevers even in the end of August and beginning of September assumed a type resembling in many respects the fever accompanying the influenza.”¶

After the disease had continued some weeks, it was observed to change its character in several places. In Dublin, Dr. Cleghorn remarked that the fever with which the influenza of 1782 was accompanied, became remittent, and sometimes intermittent; in Lincoln it was intermittent, at Stamfordham and the Isle of Man, “low and putrid.”**

We can scarcely look over the histories of influenza without perceiving a connexion between this disease and morbid affections of the mucous surface of the stomach and intestines. Thus Huxham has recorded the frequent appearance of cholera and diarrhoea in July, September, and October, after the spring influenza of 1733.†† The same author describes the “dysentaria cruenta epidemica,” which raged at Plymouth and the adjacent country, both before and after the influenza of 1743: and he adds that “he did not know whether the former disease might not be considered a translation of the latter to the intestines; but he had observed that epidemic dysentery was very rarely to be met with in the spring.”‡‡

Sir George Baker follows up his account of the epidemic catarrh of 1762 in London with a description of the epidemic dysentery which immediately succeeded it in that city;* and both he and Dr. Reynolds remarked that in 1775 diarrhoea sometimes followed the attack of influenza.†

Dr. Hamilton states that in the neighbourhood of Newcastle-upon-Tyne, “the influenza of 1782 was accompanied with colic pains and cramps in the region of the abdomen and stomach, and some had purging.”‡

In France, in the influenza of 1803, “gastric irritation was one of the most frequent complications of the disorder, and appeared in some measure to constitute an essential part of it.”§

Dr. Bertram of Hull remarked that some of the attacks of influenza in 1803 nearly resembled cholera morbus, others cynanche tonsillaris; and he goes so far as to express “a firm conviction of the three diseases being different types of the same disorder, and occasioned by the same cause.”||

Diarrhoea seems to have preceded, as an epidemic, the influenza of 1803, at Plymouth Dock, as in 1743 and 1788; for Dr. May says that early in the year “diarrhoea and cholera were very prevalent; so nearly similar to that preceding the influenza of 1788, that to many of his friends he hazarded a pretty confident opinion of an expected return; and in this he was not deceived.”¶

It must be fresh in the recollection of most that the epidemic cholera, which in a milder character appeared in many parts of Great Britain last year (1831), and is now running so fatal a career in its malignant type, was preceded by the influenza; and we know that the same herald of that formidable epidemic was seen also at Warsaw, Paris, and other places; and was lately announced even in the United States of America a short time before the cholera made its appearance in the transatlantic cities.

These facts are collected to show that there is a closer connexion between some epidemic diseases, both as to their affinity and their causes, than we commonly imagine; and that it is only by a very enlarged view of their phenomena in different countries that we can hope to improve our knowledge in this obscure branch of science.

(Thomas Hancock.)

INSANITY.—SECT. 1.—Remarks on attempted definitions of insanity.—Different varieties of the disease referred to three principal forms.

Writers on insanity are generally agreed as to the difficulty of inventing a satisfactory definition of that disease. It is perhaps impossible to comprise in a few words a charac-

teristic description of mental derangement which may prove to be of practical use; and it is not an easy matter to discover one that even includes all the essential features of the object which it is proposed to define. The latter of these requisites will be obtained if we describe insanity as consisting in "a disordered state of the functions of the brain, which gives rise to disturbances in the operations of the mind." This definition may correctly be applied to madness, but it also includes a variety of other diseases; and hence it becomes necessary to render the description more particular by exclusions and restrictions. It must be added, for example, that the disturbance in the mental operations ensuing from the morbid cause in the brain is not allied to coma or to loss of consciousness and sensibility, in order to exclude from the definition apoplexy and disorders of the same class. For a similar reason it has been common to observe that madness is a species of delirium distinct from that which is symptomatic of typhus and other febrile diseases. There are some other morbid states of the brain and of the faculties dependent for their exercise on the functions of that organ, which must in like manner be excluded by express limitations. Such are congenital idiotism, and the imbecility of old age. Now it is obvious that a definition loses all its utility when it is found necessary to encumber it with so many particular restrictions, and it is therefore better to give up the attempt to define insanity in general terms.

But the practical purpose of a definition, which is to give a clear and distinct conception of the thing to be described, will be secured if we can determine and classify the various disturbances which the mental operations undergo. These disturbances, however, present very different phenomena in different instances of the disease, and we cannot attempt to draw up a concise account of them until we have briefly noted their principal varieties.

It is generally supposed that the intellect or the reasoning faculty is principally disordered in persons labouring under mental derangement. Mr. Locke made a remark, that "madmen do not appear to have lost the faculty of reasoning; but having joined together some ideas very wrongly, they mistake them for truths, and they err as men do that argue right from wrong principles." From Mr. Locke's time it has been customary to observe that insane persons reason correctly from erroneous premises; and some instances of hallucination, or some particular erroneous impression, have been looked for as the characteristic of the disease, or an essential circumstance in it. Dr. Cullen seems to have had Mr. Locke's observation in his mind when he laid down the definition of madness which occurs in his First Lines. He describes this disease to be "in a person awake a false or mistaken judgment of those relations of things which, as occurring most frequently in life, are those about which the generality of men form the same judgment; and particularly when the judgment is very

different from what the person himself had before usually formed." Cullen attempted to draw even this description within narrower limits, by observing that "there is generally some false perception of external objects, and that such false perception necessarily occasions a *delirium* or *erroneous judgment*, which is to be considered as the disease." That this is by far too limited an account of madness, and only comprises one, and that by no means the most frequent form of mental derangement, every person must be aware who has had opportunities of extensive observation.

Of those lunatics whose intellectual faculties are manifestly disordered, there is always a considerable proportion in whose minds it is impossible to trace any particular hallucination or erroneous perception or recollection. The rapid succession of thoughts, the hurried and confused manner in which ideas crowd themselves into the mind in a state of incoherence, or without order and connection, is in very many instances among the most striking phenomena of madness. There are, likewise, cases of a different description, in which the intellectual faculties appear to have sustained but little injury, while the feelings and affections, the moral and active principles of the mind, are strangely perverted and depraved; the power of self-government is lost or greatly impaired; and the individual is found to be incapable, not of talking and reasoning upon any subject proposed to him, for this he will often do with great shrewdness and volubility, but of conducting himself with decency and propriety in the business of life. His wishes and inclinations, his attachments, his likings and dislikings, have all undergone a morbid change, and this change appears to be the originating cause, or to lie at the foundation of any disturbance which the understanding itself may have sustained, and even in some instances to form throughout the chief character or constituent feature of the disease. The older nosologists, Sauvages, Sagar, and Linnæus, were not wholly unaware of these distinctions; for in their distributions of mental diseases, we find (besides an order of *Vesania* or *Hallucinationes*, in which erroneous impressions were supposed to affect the understanding) another department styled "*Morositates*" or "*Morbi Pathetici*," consisting of depraved appetites and other morbid changes in the feelings and propensities. The disorders, however, which are classed under these heads, are not, all of them at least, strictly forms of insanity; and Pinel appears to have been the first writer who, with a clear conception of the subject, distinguished a class of maniacal affections under the term of "madness without delirium or hallucination." Pinel, who was an acute and original observer, and whose opinions carry much weight on account of his extensive opportunities of investigating the history of madness, has made the following remark in reference to the sentiments of Mr. Locke. "We may justly admire," he says, "the writings of this philosopher, without admitting his authority upon subjects not neces-

sarily connected with his inquiries. On resuming at the Bicêtre my researches into this disorder, I thought, with the above author, that it was inseparable from delirium," (meaning what is termed by English writers hallucination;) "and I was not a little surprised to find many maniacs who *at no period gave evidence of any lesion of the understanding*, but who were under the dominion of instinctive and abstract fury, as if the active faculties alone had sustained injury."

The examples given by Pinel in illustration of the above remark were not fortunately chosen, and they are all of one kind, namely, of that in which the principal phenomena of the disease were violent fits of anger or rage. The general observation which the author has so clearly enounced, that insanity consists, in certain cases, in a morbid perversion of the affections and moral feelings exclusively, and without any perceptible lesion of the intellectual faculties, is a fact of the highest importance pathologically and practically, and the opinion of Pinel in this particular deserves the most attentive consideration. It will be found that later practical writers, though they have not made the same statement in so decided a manner, have yet given a testimony which leads to the same result. The following remarks by M. Esquirol, who is less systematic than Pinel, prove that he was led to a similar conclusion by the strict observation of facts.

"The insane conceive an aversion for those persons who are most dear to them, revile them, ill-treat them, anxiously shun them, in consequence of their mistrust, their suspicions, and their fears. Prejudiced against every thing, they are afraid of every thing. A few appear to form an exception to this general rule, in preserving a sort of affection for their relatives and friends; but this feeling of attachment, which is sometimes excessive, subsists without confidence in those persons who before the attack of disease had been the directors of the thoughts and actions of the patient. A melancholic, who is devotedly attached to his wife, is deaf to her counsels and advice. A son would sacrifice his life for his father, but will not make the slightest attempt, in compliance with the entreaties of the latter, to overcome the morbid impression which occasions him so much grief."

"This moral alienation is so constant," says M. Esquirol, "that it appears to me to be the proper characteristic of mental derangement. There are madmen in whom it is difficult to discover any trace of hallucination, but there are none in whom the passions and moral affections are not disordered, perverted, or destroyed. I have in this particular met with no exceptions."

"A return to the proper and natural state of the moral affections," says the same writer, "the desire of seeing once more children or friends; the tears of sensibility; the wish manifested by the individual to open his heart and return into the bosom of his family, to resume his former habits, afford a certain indica-

tion of cure, while the contrary dispositions had been a mark of approaching insanity, or the symptom of a threatened relapse. This is not the case when there is merely a disappearance of the hallucination, which then only is a certain sign of convalescence, when the patients return to their natural and original affections."*

If the opinion expressed by these writers is founded on real facts,—and that it is so the writer of the present article is well assured from ample proofs afforded by his own observation,—it must be evident that it leads to very important results. It will be necessary, in conformity with it, and with the varieties of phenomena which the disease really presents, to classify the different forms of madness or insanity under the following divisions.

1. Moral insanity, or madness consisting in a morbid perversion of the natural feelings, affections, inclinations, temper, habits and moral dispositions, without any notable lesion of the intellect or knowing and reasoning faculties, and particularly without any maniacal hallucination.

2. Intellectual insanity, or madness attended with hallucination; in which the insane person is impressed with the belief of some unreal event as of a thing which has actually taken place, or in which he has taken up some notion repugnant to his own experience and to common sense, as if it were true and indisputable, and acts under the influence of this erroneous conviction.

3. There is another well-marked division of maniacal cases, in which the whole mind, if we may use the expression, seems to be equally deranged. The most striking phenomena in this form of the disease are the rapidity and disorder with which the ideas follow each other, almost without any discoverable connexion or association, in a state of complete incoherence and confusion. It is impossible to fix the attention of the patient long enough to obtain a reply to the most simple question. His understanding is wholly lost in the constant hurry of ideas which crowd themselves upon him, and which appear to exceed the power of distinct utterance, while his habits betray a corresponding degree of restless activity and extravagance.

The most appropriate designation in our language for this species of disease is *incoherent madness*, a term given to it long ago by Dr. Arnold. It is named by Pinel *dementia* or *démence*, dementedness. Pinel has given an admirable definition of it: "Rapid succession, or uninterrupted alternation of insulated ideas, and evanescent and unconnected emotions; continually repeated acts of extravagance; complete forgetfulness of every previous state; diminished sensibility to external impressions; abolition of the faculty of judgment; perpetual activity."

If we are correct in assuming that all the varieties of mental derangement may find their place under one of the three descriptions we

* Esquirol, Dict. des Sc. Méd., tom. xvi.

have thus marked out, a definition or short nosography of madness will be furnished by enumerating the characteristics of the three forms. We may then describe insanity as "a chronic disease manifested by deviations from the healthy and natural state of the mind; such deviations consisting either in a morbid perversion of the feelings, affections, and habits, or in disturbances of the intellectual faculties, under the influence of which the understanding becomes susceptible of hallucinations or erroneous impressions of a particular kind; or, thirdly, in a state of mental incoherence, or constant hurry and confusion of thoughts."

We shall now endeavour to trace an accurate description of the actual phenomena of insanity, containing the results of long and attentive observation. In discriminating the different varieties of the disease, we shall neither deviate further than is necessary from the arrangements of former writers, nor shall we follow in every respect the nosological divisions which they have adopted. The reader will, if we are not mistaken, find data in the following outline sufficient to confirm and illustrate the preceding remarks, and to shew how far the distinctions we have endeavoured to establish are complete.

SECT. II.—*Phenomena of madness described.*

1. *First appearances of the disease.*—The first appearances of madness are very different in the various forms of the disease and in different cases. Sometimes the complaint breaks out at once, without any previous indications; the manners of the patient are observed to be unusually impetuous; his conversation hurried; his mind full of projects, which he pursues with restless activity. He betrays the absolute derangement of his understanding by announcing some false and absurd impression, or by acting upon it. When his attempt is resisted, or when by accident he explains the motive which incited him, his condition is at once made evident, and the necessity of restraint becomes obvious. Such is the mode in which insanity makes its attack in the greater number of cases. In other instances the actual appearance of disturbance in the intellect is preceded by a period of uncertain duration, in which an unsound state of mind exists, but displays itself in a different manner. A certain waywardness or singularity of character, an unsteadiness in pursuits and inclinations, a fickleness or capriciousness of temper and habit, is observed for some time before the individual is set down by his relatives as a lunatic. This stage of the disease may last for years. M. Pinel mentions the case of a man who believed his wife to have been deranged only six months, at the commencement of which period she had sustained an attack of violent mania, but after repeated inquiries was at length convinced that she had not been in a sound state of mind for fifteen years. The same writer likewise observes that in many instances the origin of mental derangement has been referred, on tracing its history, to a

period of four, ten, or even of fifteen or twenty years before the time when it became fully manifest, or when a disordered state, previously ambiguous, changed its character into that of ordinary or decided mania.

Cases of disease affecting the mind, such as we have described, and in which the succession of symptoms and the development of the complaint follow the order just pointed out,—a certain period either of melancholy dejection or of morbid excitement, attended with a disturbed and unnatural state of the feelings, temper, and habits, preceding, and after a time ushering in a clearly marked attack of insanity—are in fact only examples of a transition from one form or state of mental disorder to another, which is more strongly characterised and more easily distinguished. There are, however, numerous instances in which phenomena similar to those of the previous stage last for many years, perhaps during life, sometimes maintaining their ambiguous and undefined character, at others becoming aggravated in degree, but without undergoing a transition into the peculiar form of madness attended with marked disturbance of the intellectual faculties. Of this description are the cases of mental disease which we purpose to distinguish under the term of moral insanity.

2. *First form of the disease.*—*Moral insanity.*—This form of mental disease has been said above to consist of a morbid perversion of the feelings, affections, habits, without any hallucination or erroneous conviction impressed upon the understanding; it sometimes co-exists with an apparently unimpaired state of the intellectual faculties.

There are many individuals living at large, and not entirely separated from society, who are affected in a certain degree by this modification of insanity. They are reputed persons of singular, wayward, and eccentric character. An attentive observer may often recognise something remarkable in their manner of existence, which leads him to entertain doubts as to their entire sanity, and circumstances are sometimes discovered on inquiry which assist in determining his opinion. In many instances it is found that there is an hereditary tendency to madness in the family, [or that several relatives of the person affected have laboured under other diseases of the brain. The individual himself is discovered in a former period of life to have sustained an attack of madness of a decided character. His temper and dispositions are found on inquiry to have undergone a change; to be not what they were previously to a certain time; he has become an altered man, and this difference has perhaps been noted from the period when he sustained some reverse of fortune, which deeply affected him, or since the loss of some beloved relative. In other instances the alteration in his character has ensued immediately on some severe shock which his bodily constitution has undergone. This has been either a disorder affecting the head, a slight attack of paralysis, a fit of epilepsy, or some fever or

inflammatory disorder which has produced a perceptible change in the habitual state of the constitution. In some cases the alteration in temper and habits has been gradual and imperceptible, and it seems only to have consisted in an exaltation or increase of peculiarities which were always more or less natural or habitual.

In a state such as that above described many persons have continued for years to be the sources of apprehension and solicitude to their friends and relatives. The latter in many instances cannot bring themselves to admit the real nature of the case. The individual follows the bent of his inclinations; he is continually engaging in new pursuits, and again relinquishing them without any other motive than mere caprice and fickleness. At length the total perversion of his affections, the dislike and even enmity manifested towards his dearest friends excite greater alarm. When it happens that the head of a family labours under this ambiguous modification of insanity, it is sometimes thought necessary from prudential motives, and to prevent absolute ruin from thoughtless and absurd extravagance, or from the result of wild projects and speculations, in the pursuit of which the individual has always a plausible reason to offer for his conduct, to make some attempt with the view of taking the management of his affairs out of his hands. The laws have made inadequate provision for such contingencies, and the project is often unsuccessful. If the matter is brought before a jury, and the individual gives pertinent replies to the questions that are put to him, and displays no particular hallucination,—a feature which is ordinarily looked upon as essential to madness,—it is most probable that the suit will be rejected.

Several practical writers have left a testimony, which is sufficiently conclusive, as to the existence of moral insanity, though they have not designedly and in set terms marked it as a distinct form of the disease.

We have already observed that M. Esquirol has stated his opinion to be, that moral alienation, or a perverted state of the affections, is, rather than intellectual aberration, the characteristic of mental derangement. M. Georget likewise describes the state we have alluded to as a particular modification of madness. He observes "that individuals predisposed to mental disease by a faulty education or by previous attacks, have often continued for a long time, or perhaps even during their whole lives, to attract observation by caprices in their deportment, by something eccentric in their manner and habits of life, by an ill-regulated fondness for pursuits of the fancy, and the mere productions of the imagination, combined with a striking inaptitude in the study of the exact sciences." The last-mentioned particular will scarcely be allowed to constitute a characteristic trait of madness in this country, whatever may be the case in France. "These persons are noted," continues the same writer, "for singularity of opinions, of conduct, for transitory fits of in-

telligence, or sallies of wit, which are too strongly contrasted with their habitual state of nullity or monotony; by a levity in thoughts, a weakness in judgment, a want of connexion in their attempts at reasoning. Some individuals are presumptuous, desirous of undertaking every thing, and capable of applying themselves to nothing; others are extravagant and mobile in the utmost degree in their opinions and sentiments; many are susceptible, irritable, choleric, and passionate; some are governed by pride and haughtiness without bound; a few are subject to vague anxieties or to panic terrors."

It must be observed that, although M. Georget has described this state of disease as a first stage, or as the period of what he terms with M. Esquirol the *incubation* of madness, yet, as he says that it often lasts through the life of the individual, we may consider his testimony as given, in point of fact, in favour of the real existence of moral insanity as a particular modification of disease.

Individuals labouring under this disorder are capable of reasoning or supporting an argument on any subject within their sphere of knowledge that may be presented to them, and they often display great ingenuity in giving reasons for their eccentric conduct, and in accounting for and justifying the state of moral feeling under which they appear to exist. In one sense, indeed, their intellectual faculties may be termed unsound, but it is the same sense in which persons under the influence of strong passions may generally be said to have their judgment warped, and the sane or healthy exercise of their understandings impeded. They think and act under the influence of strongly excited feelings, and a person accounted sane is under such circumstances proverbially liable to error both in judgment and conduct.

We have already had occasion to observe that the existence of moral insanity as a distinct form of mental derangement has been recognized by Pinel. The following example recorded by that writer is a characteristic one:

"An only son of a weak and indulgent mother was encouraged in the gratification of every caprice and passion of which an untutored and violent temper was susceptible. The impetuosity of his disposition increased with his years. The money with which he was lavishly supplied removed every obstacle to the indulgence of his wild desires. Every instance of opposition or resistance roused him to acts of fury. He assaulted his adversary with the audacity of a savage; sought to reign by force, and was perpetually embroiled in disputes and quarrels. If a dog, a horse, or any other animal offended him, he instantly put it to death. If ever he went to a fête or any other public meeting, he was sure to excite such tumults and quarrels as terminated in actual pugilistic rencontres, and he generally left the scene with a bloody nose. This wayward youth, however, when unmoved by passions, possessed a perfectly sound judgment.

When he became of age, he succeeded to the possession of an extensive domain. He proved himself fully competent to the management of his estate, as well as to the discharge of his relative duties, and he even distinguished himself by acts of beneficence and compassion. Wounds, law-suits, and pecuniary compensations were generally the consequences of his unhappy propensity to quarrel. But an act of notoriety put an end to his career of violence. Enraged with a woman who had used offensive language to him, he precipitated her into a well. Prosecution was commenced against him, and on the deposition of a great many witnesses, who gave evidence to his furious deportment, he was condemned to perpetual confinement in the Bicêtre."

The morbid and irregular excitement of the active propensities, and the total want of self-control, which are so conspicuous in moral insanity, display themselves in various ways. Almost every passion or feeling of the mind gives in different cases the character to the disease when displayed under a certain modification which it would not be easy to describe in accurate terms. Violent gusts of passion breaking out without cause, and leading to the danger or actual commission of serious injury to surrounding persons, are the features of disease in most of the cases mentioned by Pinel. These were examples of madness, consisting in intense irascibility without lesion of the understanding. There are other instances in which malignity has a deeper die. The individual, as if actually possessed by the demon of evil, is continually indulging enmity and plotting mischief, and even murder, against some unfortunate victim of his malice. When this is connected with the false belief of some personal injury actually sustained, the case does not fall under the head of moral insanity simply so termed. It involves hallucination or erroneous conviction of the understanding. But when the morbid phenomena include merely the expressions of intense malevolence excited without ground or provocation, actual or supposed, the case is strictly one of moral madness. And such instances are more frequent than it will be easy for many persons to believe.

Some maniacs display their condition by a propensity to commit every species of mischief, though devoid of any feeling of malevolence. A case of this description, strongly marked, was lately pointed out to the writer of this article in the York Lunatic Asylum, by Dr. Wake, the able and intelligent physician to that institution. The individual is a youth of good temper, cheerful and active, having no defect of intellect whatever that could be discovered, even after long observation. He is continually prone to commit every kind of mischief in his power; and not long ago escaped from his confinement and made his way to Bishop-Thorpe Palace, with the design to set it on fire. Dr. Wake has given his assurance that several cases have occurred precisely similar to that above related in all essential symptoms, during his attendance at the

asylum, which has continued seventeen years, and that he considers no point in the history of madness better established by facts than the existence of moral insanity strictly and exclusively so termed, and in conformity with the definition above laid down.

A large number of cases falling into this division of diseases are those in which a disposition to melancholy and dejection of mind exists, without any illusion of the understanding connected with it. A constant feeling of gloom and sadness clouds all the prospects of life: the individual, though surrounded with all the comforts of existence, and even, exclusively of his disease, suffering under no internal source of disquiet, at peace with himself, with his own conscience, with his God, yet becomes sorrowful and desponding. All things present and future are to his view involved in dreary and hopeless gloom. This tendency to morbid sorrow and melancholy, as it does not destroy the understanding, is often subject to controul when it first arises, and probably receives a peculiar character from the previous mental state of the individual, from his education, and his religious or irreligious character. Persons of well-regulated minds, when thus affected, express grief and distress at the inaptitude of which they are conscious to go through the active duties of life: frequently they feel a horror of being driven to commit an act of suicide or some other dreadful crime. This idea haunts them and renders them fearful of being a moment alone. It, however, subsides, and such cases often terminate in recovery. Persons of an opposite character give themselves up to *tadium vite*, to morose disgust; they loathe their very existence, and at length, unless prevented, put an end to it.

A propensity to theft is often a feature of moral insanity, and sometimes it is the leading if not the sole characteristic of the disease. The writer of this article has lately seen a lunatic, confined in an asylum, who would only eat when he had stolen food, and his keeper made it a constant practice to put into some corner within his reach various articles destined for his sustenance, in order that he might discover and take them furtively. Many instances are upon record of individuals noted for a propensity to steal, without the desire of subsequent possession, though in other respects of sound mind, or at least not generally looked upon as deranged. Probably some of these would afford, if accurately scrutinized, examples of moral insanity, while others might be found referable to eccentricity of character. The discrimination—if indeed the two things are essentially different—could only be made in particular instances by taking into the account a variety of circumstances, such as the hereditary history of the individual and his consanguinity with persons decidedly insane, his former character and habits, and the inquiry whether he has undergone a change in these respects at some particular period of his life.

This form of insanity has been, if we are not mistaken, in many instances the real source of

moral phenomena of an anomalous and unusual kind, and of certain perversions of natural inclination which excite the greatest disgust and even abhorrence.

In some instances moral insanity displays itself in a want of self-government, in a continual excitement, and unusual expression of feeling, or in thoughtless and extravagant conduct. A female, modest and circumspect, becomes violent and abrupt in her manners, loquacious, impetuous, talks loudly and abusively against her relations and guardians, before perfect strangers. Sometimes she uses indecent expressions, and betrays without reserve unbecoming feelings and trains of thought. Not unfrequently persons affected with this form of disease become drunkards; they have an uncontrollable desire for intoxicating liquors, and a debauch is followed by a period of raving madness, during which it becomes absolutely necessary to keep them in confinement. Individuals are occasionally seen in lunatic asylums who under such circumstances have been placed under controul. After the raving fit has passed off, they demand their release; and when they obtain it, at the first opportunity resort to their former excesses, though perfectly aware of the consequences which await them.

A form of mental disease has been described by some writers, which, though not of frequent occurrence, is occasionally seen, and is well known to those who have extensive means of observation. It is peculiar to old age, and has been termed *delirium senile*, and by Dr. Burrows, who has accurately distinguished it, *senile insanity*. It constitutes a variety of moral insanity.

This disordered state makes its appearance in old men who have never before been insane or suspected of any tendency to mental derangement. It consists, like other forms of moral insanity, in a morbid excitement of passions and a remarkable perversion of the temper and propensities. The whole moral character of the person is changed. "The pious," says Dr. Burrows, "become impious, the content and happy discontented and miserable, the prudent and economical imprudent and ridiculously profuse, the liberal penurious, the sober drunken." In some elderly persons impulses which had long been effete become of a sudden excited, and a strong tendency to vicious habits is displayed. "In fact the reverence which age and the conduct suited to it always command, is converted into shame and pity at the perversion of those moral and social qualities which, perhaps, have hitherto adorned the patient's declining days." This description coincides accurately with the character of moral insanity. There are instances, though rare, of the appearance of hallucinative madness in old persons, but the case we have now described is of a different character, and consists in a disordered condition of the moral or active powers alone.

The following cases will afford some observations illustrative of the history of moral insanity.

J. K—, a farmer, several of whose relatives had been the subjects of mental derangement, was a man of sober and domestic habits, and frugal and steady in his conduct, until about his forty-fifth year, when his disposition appeared to have become suddenly changed in a manner which excited the surprise of his friends and neighbours, and occasioned grief and vexation in his family. He became wild, excitable, thoughtless, full of schemes and absurd projects. He would set out and make long journeys into distant parts of the country to purchase cattle and farming-stock, of which he had no means of disposing; he bought a number of carriages, hired an expensive house ready furnished, which had been inhabited by a person much above his rank, and was unsuitable to his condition; he was irascible and impetuous, quarrelled with his neighbours, and committed an assault upon the clergyman of the parish, for which he was indicted and bound to take his trial. At length his wife became convinced that he was mad, and made application for his confinement in a lunatic asylum, which was consequently effected. The medical practitioners who examined him were convinced of his insanity by comparing his late wild habits and unaccountable conduct with the former tenor of his life, taking into consideration the tendency to disease which was known to prevail in his family. The change in his character alone had produced a full conviction of his madness in his friends and relatives. When questioned as to the motives which had induced him to some of his late proceedings, he gave clear and distinct replies, and assigned with great ingenuity some plausible reason for almost every part of his conduct. After a period of time passed in great seclusion, his mind became gradually tranquillized; the morbid excitement of his temper and feelings disappeared; he was set at liberty, and has since conducted himself with propriety.

A brother of the above patient has been at two different times confined in the same asylum, labouring under symptoms of derangement in all essential particulars resembling those above detailed. His disorder has consisted chiefly in morbid excitement, wildness and irregularity of conduct, differing from his usual habits and character, without any hallucination or disturbance of the intellectual faculties. He has on both occasions remained in the asylum until he was fully convalescent, and after his departure has acknowledged his conviction that he had been deranged, and in a state requiring control and seclusion from society.

Abraham B—, a working tradesman, of industrious and sober habits, conducted himself with propriety until about forty-six years of age, and had accumulated a considerable property from the fruits of his exertions. About that period he lost his wife, and after her death became more and more penurious. At length he denied himself the comforts, and in a great measure even the necessities of life, and became half-starved and diseased; his body was emaciated and beset with scaly eruptions. Mr. S—, a gentleman who had long known

him, hearing of the condition into which he had sunk, sent a medical practitioner to visit him, by whose advice B—— was removed from a miserable dirty lodging to a lunatic asylum. Mr. S——, who was present on the occasion, observed that Abraham B——, previously to his quitting the room in which he had immured himself, kept his eyes fixed on an old trunk in the corner of the apartment. This was afterwards emptied of its contents, and in it were found, in the midst of various articles, dirty bank notes, which had been thrown into it apparently at different times, to the value of more than a thousand pounds. Abraham B——, after his removal to an asylum, where he had wholesome food and exercise, soon began to recover from his bodily infirmities, and at length became anxious to be at large. The writer of this article visited him, and conversed with him for some time, in order to ascertain his mental condition. He betrayed no sign of intellectual delusion, nor did it appear that any thing of that description had ever been a part of his complaint. His replies to questions were rational according to the extent of his natural capacity. He was determined to go and manage his property, and get a wife who should take care of him. In a few days after his release he was married to a servant belonging to the lunatic asylum where he had been confined. His new wife found after some months that it was impossible to endure the strange conduct of her husband, and after trying various expedients, brought him back to the asylum, with a certificate from a medical man, who had examined him and declared him to be insane. He still remains in confinement, and his derangement is now more complete than formerly, as it plainly involves his intellect. He now raves against his wife, declares that she is married to her own brother, vows bitter revenge for the injuries he has sustained, and vehemently demands his release whenever he is visited by the inspecting magistrates.

Abraham B——'s case was at first merely a perversion of moral habits. If the real nature of this case was otherwise in any degree doubtful, it is rendered obvious by the more decided madness which has since appeared. Very clear indications of a disturbed intellect appeared in his manners and expressions soon after the commencement of his second confinement.

It is probable that many instances of extreme avarice and penury, as those of Elwes and Dancer, and other celebrated misers, were in reality cases of disease. Whether such individuals were proper objects for confinement is quite another question. In the case of Abraham B—— the interference of others was necessary in order to preserve his existence.

The cases above detailed resemble each other in many particulars, and especially in the circumstance that the morbid perversion of habits which characterised each of them took its rise without any cause that could be distinctly traced. In the following instance the appearance of analogous derangement was preceded and probably caused by constitutional disease,

and by the suppression of a long-continued and habitual discharge from the lungs.

The case we are about to relate is a tolerably characteristic example of moral insanity. During one period of its course, when aggravated by temporary circumstances, it indicated some tendency to assume the form of monomania. The patient displayed a proneness to suspicion, and to entertain unfounded impressions connected with the motives and characters of individuals. But these impressions never became deeply fixed or took a permanent hold of the mind, and they soon disappeared. For some years both previously and subsequently to the period alluded to, the complaint wore that appearance which has, we trust, been correctly designated under the term prefixed to the present section.

The account of this case is but slightly abridged from a narrative drawn up by a near relative of the patient.

A. M—— is a maiden lady, aged about 48, of short stature, and somewhat deformed; her natural disposition was steady and industrious. She accomplished her undertakings by dint of application rather than by energetic or sudden efforts. She was constant rather than ardent in her attachments, free from resentment, never the subject of lively emotions; a great respecter of truth, just and very exact in all that she said or did. Her charitable acts were commensurate with her means, deliberate, and the result of principle rather than arising from the mere impulse of compassionate feeling. She was cautious and reserved in her communications, and scarcely if ever formed any familiar and particular intimacies with young persons of her own sex. Being debarred by her infirmities from associating with the young and active, she seemed more like an adult member of the family than a child. She was very clever in arithmetic and in all matters of business, and was fond of regulating and controlling the little affairs of those who formed the domestic circle surrounding her. Young persons and servants, finding that they derived advantage from her advice, generally gave her an opportunity of gratifying her inclination. Her dress, which was always plain and in good taste, was to her an object of greater attention than it often is to persons of fashion.

In March 1822 she was attacked by severe inflammation in the lungs, attended by expectoration of bloody mucus. This was the first time in her life when it was necessary to confine her to bed. She submitted with great reluctance to the restrictions that were needful for her recovery, and would not be persuaded until she had heard the opinion of an old friend of her family, who is a medical practitioner, that the means adopted were proper and required by her case. She was then, however, in a great measure reconciled, and after seven or eight weeks was so far recovered as to bear a removal into her native county. At this period nobody believed that she would survive another winter. Her restoration to her usual state of health was very slow, and her sister, who was her constant companion, perceived with sorrow

that her temper was now much changed. She appeared restless, always wishing to go somewhere, or to do something to which she was unequal; becoming unjustly irritated when she could not urge her sister, whose health and spirits were declining, to fall in with her ideas, and occasionally giving way to reproaches which were keenly felt. She tried every method of persuasion to induce her sister to go to the neighbourhood of London, though for the preservation of her life the latter had been obliged to give up the custom of spending the winter there, and the attempt was considered dangerous to her. Every inducement, every argument was suggested to promote this favourite object: other towns were too warm and too cold, too hilly, too much intersected with water, too foggy. In 1827 she determined to go without her sister to H——, near London. She went, and from her letters her sister perceived that she was living in a state of excitement far surpassing that of her former habits; paying short visits to friends in the surrounding villages, going out in the common short stages, without so much regard to weather as was usual to her even in the summer; receiving small parties at home, attending a very crowded church, writing a great many letters, &c. &c. She used to write to her sister in rather a boastful style, frequently mentioning her good health and high spirits, as if to justify her choice of a residence near the metropolis. When the sisters met during the summer at their house in —shire, her high spirits were gone, she looked more aged than the time elapsed would have led any one to expect, took less interest in her garden, appeared exhausted, and, without contributing her share to the conversation, used frequently to sleep in her chair. She lay much in bed, nursed herself up, and in October went again to H——, as much agog as ever. Another winter passed much as the preceding one had done. She spoke much again of her high spirits, visited much, was observed to be unusually liberal in her presents to most of her acquaintances. A second summer of inertness was succeeded by a winter at H——. She was now weak, indisposed for visiting, and, in fact, so much worse as to be unable to follow her inclinations. In the spring of 1830 she had an attack of the same nature as that in 1822, but not so severe or lasting. In the summer she was nearly as before, and quite as eager to resume her plans, as enthusiastic in her commendations of every body and every thing at H——.

About this time some riots took place in London, and more were apprehended. She now expressed herself as apprehensive that "very awful times were at hand," wrote frequent letters to her sister full of indecision, and expressive of distrust in her servants, her host and his family. A friend who called upon her "was shocked to find her in so low a way." He thought her unfit to be alone, and she was unwilling to adopt any plan for leaving her lodgings, or having any one with her. She said she should be happy with her sister, and knew that she should be taken care of by the latter,

but dreaded becoming a burden to her and making her ill; yet feared that if she did not go to her sister, "some one would put her where no one would know, and cause her to sign papers which she ought not to sign." She was evidently apprehensive of being sent to a lunatic asylum. She thought her host was a writer of "*Swing letters*,"* and dreaded that he might fill the house with combustibles and blow it up with her in it. A medical man who was taken to see her, said that she was in a state of great mental excitement, and ought to be taken to her sister as soon as possible. The frost was severe when she was escorted to her sister, who was then settled at Bristol, yet she took no cold, experienced no injury from fatigue, and lost that feeling of terror to which she had for some time been subject. Since she has been with her sister, she has been increasingly obstinate, suspicious, undecided, restless, parsimonious even to meanness, indisposed to any employment bodily or mental, except as far as relates to a most troublesome interference with the most minute actions of others. Could she have her own way, she would control the food, dress, and employment of every one near her. She has become negligent in dress, and comparatively dirty in her habits, yet has an insatiable desire for new clothes, which she never finds the right time to wear. She is constantly predicting her utter ruin, is sure she will not have money enough to live until such and such a time; knows that enough will not be found to pay Dr. —; knows he will not let any one of so shabby an appearance be long in his house; does not know where she shall go when he is tired of her; thinks that "it is the devil that makes her behave as she does;" "that her heart is hardened to do what she ought not to do;" "she is like the man spoken of in the Gospel, who could not be bound even with fetters." She sees people look at her; hopes they don't think she drinks too much; is quite sure she never did. These impressions are continually varying; but no sooner is her mind tranquillized on one subject than another source of disquietude arises, so that she exhausts every person who is long with her. Her bodily health is better than it was for years previous to her mental derangement. A constitutional asthma, to which she has been subject from the age of six or seven years, has nearly subsided, and the habitual profuse expectoration has considerably diminished. She wears less clothing, and appears less sensible to cold or damp than heretofore.

The writer of this article has had several interviews with the subject of the foregoing relation, during some of which she gave replies to a variety of questions referring to the past and actual state of her health, both bodily and mental. No impression could be traced in her mind that bore the character of maniacal hallucination. The circumstance most observable

* It may hereafter require to be explained that, about the period above mentioned, the threatening letters of incendiaries in various parts of the country frequently bore the signature of *Swing*.

in her condition was a perpetual disposition to find fault with every action, even the most trivial, that was witnessed by her. When asked if she was not aware of this propensity, she seemed to give an unwilling affirmative to the question, and she was plainly aware of the fact, for on the inquiry being made whether the habit had only existed of late years, or had been a part of her natural character, she steadily averred that such was not her natural disposition, "that she was formerly very different."

The preceding cases present no great difficulty as to the conclusion to be adopted respecting the nature of the disorder; such, at least, was the opinion of all the medical practitioners who examined personally the individuals. We now proceed to mention an instance of moral peculiarity which will not allow of so decided an opinion.

Miss A. N—— is a maiden lady of very singular aspect and manners. She has for many years estranged herself from nearly all the friends of her family, formerly a large circle, and associates almost exclusively with her domestics, and one relative who lives with her. Her chief amusement and delight is to invent and relate the most unfounded, and sometimes the most absurd and ridiculous stories. Sometimes she has displayed mortification when in danger of being detected in the invention of these falsehoods, or when questioned respecting them. Her expression of countenance is sometimes very wild and peculiar. She has never shewn any decided mark of mental derangement, nor is she considered as insane, though it has frequently been observed by those who have known her, "that they should not at any time be surprised to hear of her being mad."

No person would venture to pronounce this lady to be insane, or at least to found any proceeding upon the opinion; and yet it is highly probable that her eccentricity depends upon constitutional peculiarity. One of her parents was decidedly insane during a considerable period of life, and the other, as well as several ancestors and relations by blood, laboured under diseases of the brain, of which fatuity in different degrees was the result.

It is generally admitted that there are few questions which physicians are called upon to decide, of more difficult determination than that which relates to the existence or non-existence of insanity in examples which present no obvious and clearly discoverable disturbance in the state of the intellectual faculties. It may be apprehended that the perplexities with which this subject has been environed, will rather be increased than diminished by the recognition of a form of mental derangement admitting the designation here adopted. But the real facts of a difficult question must be known and described in their true relations, before a solution can be sought with any prospect of advantage; and if we are not mistaken in the view of this subject and the facts connected with it, which we have adopted, it will be found that something is gained by admitting a position which places the inquiry relative to the existence of insanity in a different light from

that in which it has most frequently been regarded.

Those who are interested in studying the relations of this disease will do well to consult the able and well-known work of Dr. Conolly. The question how far persons labouring under merely moral insanity are incapacitated for sustaining the relations of society, belongs to medical jurisprudence.

3. *Second form of insanity. Madness attended with hallucination.*—We now proceed to varieties of disease which are of far more easy discrimination than that species of madness which involves merely a perversion of the moral affections and habits. When the patient is found to labour under a disturbed condition of the understanding, when a morbid delusion or hallucination is impressed upon his mind, no doubt can be entertained as to the actual existence of insanity. By the term *hallucination* we mean to express what Cullen and Pinel denote by that of delirium, viz. a belief of unreal events or relations, apprehended under the influence of disease to be actual and real, or some notion repugnant to common sense, impressed upon the mind as true and indisputable, the patient acting under the influence of his erroneous conviction.

There are two very different states of disease attended with this symptom. In one the understanding is, when exercised on many subjects, comparatively clear, and the morbid impressions are partial; in the other, the disturbed condition of the intellectual faculties involves all the operations of the mind. These states are respectively termed monomania, and mania or ordinary mania. Each of them requires a separate consideration.

Of Monomania.—Cases of partial insanity have been by former writers distinguished by the term melancholia, and it has been supposed that a majority of them are of the description by which that term was suggested, involving gloomy impressions and dejection of mind: the designation of mania has been at the same time applied to raving madness, or insanity accompanied by violent excitement. This distinction is laid down in the most explicit terms by Van Swieten. "A mania distinguitur melancholia, quod nondum adsit sævus ille furor, qui in maniacis observatur. Præterea et illud signum diagnosticum melancholice est, quod uni et eidem cogitationi pertinacissime inhæreant tales ægri, et fere circa hanc illamve opinionem delirant tantum; in reliquis omnibus sanam ostendunt mentem et sæpe acutissimum ingenium." It was well observed by M. Esquirol, that the distinction connected with this appropriation of terms is not uniformly supported by facts, as the impressions of partial madness are not always of a gloomy character: the mind, in this form of disease, is not in every instance abandoned to sorrow and melancholy. The term monomania, meaning madness affecting one train of thought, or involving only a single morbid impression, was on these considerations substituted, and has generally been adopted of late times instead of melancholia.

The notion, however, which many persons

entertain as to the nature of the disease thus designated, is very far from being in general correct. It is supposed that the mind is perfectly sound when its faculties are exercised on any subject unconnected with a particular impression which constitutes the entire disease. Cases are on record which, if faithfully recorded, fully come up to this description. In general the real character of monomania is very different. The feelings and affections are in that state which has been described under the head of moral insanity, and on this it would appear that some hallucination or maniacal delusion has supervened. The following case will serve to illustrate the observation which we have just made.

Mr. E. W., a gentleman about thirty years of age, has laboured for several years under symptoms of moral insanity. He has been long dejected in spirits and morose in temper, dissatisfied with himself, and suspicious of all that surrounded him. He was capricious and unsteady in his pursuits, frequently engaging in some new study in the most sanguine manner, and soon abandoning it in despair of making any progress, though possessed of good talents and considerable acquirements of knowledge. He passed the requisite period of time at one of the Universities, but could not be prevailed upon to go in for his degree, either through timidity and want of resolution, or, as it was conjectured by his friends, from a morbid apprehension that the examiners would not deal fairly with him and award him the station to which he aspired and believed himself entitled. He applied himself afterwards to the study of medicine, and then to that of metaphysics, and speedily relinquished both. He frequently changed his residence, but soon began to fancy himself the object of dislike to every person in the house of which he became the inmate. His peculiarities appearing to increase, he was visited by two physicians, who were desired to investigate the nature of his case. On being questioned narrowly as to the ground of the persuasion expressed by him, that he was disliked by the family with which he then resided, he replied that he heard whispers uttered in distant apartments of the house indicative of malevolence and abhorrence. An observation was made to him that it was impossible for sounds so uttered to be heard by him. He then asked if the sense of hearing could not, by some physical change in the organ, be occasionally so increased in intensity as to become capable of affording distinct perception at an unusual distance, as the eyes of mariners are well known to be accommodated by long effort to very distant vision. This was the only instance of what might be termed hallucination discovered in the case after a minute scrutiny. It seemed to be a late suggestion. The individual had been for years labouring under a gradually increasing moral insanity. His judgment had become at length perverted by the intensity of his morbid feelings, and admitted as real an erroneous impression, suggested by his fancy, which happened to be in harmony with his feelings, and served to account for them.

There are, indeed, cases of insanity attended with hallucination on a constant erroneous impression, in which this symptom will appear to many persons to afford but little evidence as to the real nature of the complaint. The delusive impression appears to be so blended with the prevalent disorder of the feelings and affections, or it seems to be so much the result of the peculiar circumstances by which the patient is surrounded, that it is scarcely contemplated as a distinct and peculiar phenomenon. These remarks will receive illustration from the following case.

Mr. H. P. — had been for many years confined in a lunatic asylum, when, an estate having devolved upon him by inheritance, it became necessary to subject him anew to an investigation. He was examined by several physicians, who were unanimous in the opinion that he was a lunatic; but a jury considered him to be of sound understanding, attributing his peculiarities to eccentricity, and he was consequently set at liberty.

The conduct of this individual was the most eccentric that can be imagined: he scarcely performed any action in the same manner as other men; and some of his habits, in which he obstinately persisted, were singularly filthy and disgusting. For every peculiar custom he had a quaint and often ludicrous reason to allege, which indicated a strange mixture of shrewdness and absurdity. It might have been barely possible to attribute all these peculiarities, as well as the morbid state of temper and affections, to singularity in natural character and to the peculiar circumstances under which this person had been placed. But there was one conviction deeply fixed on his mind, which, though it likewise might be explained by the circumstances of his previous history, seemed to constitute an instance of maniacal delusion. Whenever any person whom he understood to be a physician attempted to feel his pulse, he recoiled with an expression of horror, and exclaimed, "If you were to feel my pulse, you would be lord paramount over me for the rest of my life." The result has proved that confinement is not always necessary in cases of this description. Mr. H. P. — has remained at liberty for many years, and his conduct, though extremely singular, has been without injury to himself or others.

We shall conclude our observations on this subject by the record of a remarkable case which illustrates the tendency of moral insanity to degenerate into, or ultimately assume, the character of monomania. The individual who was the subject successively of these forms of disease, was for several years in a state which gave rise to apprehension in many of his friends, while some who narrowly observed him were fully convinced of his insanity. The disease at length broke out in a form which admitted of no doubt.

A gentleman remarkable for the warmth of his affections, and the amiable simplicity of his character, possessed of great intellectual capacity, strong powers of reasoning, and a lively imagination, married a lady of high mental

endowments, and who was long well known in the literary world. He was devotedly attached to her, but entertained the greatest jealousy lest the world should suppose that, in consequence of her talents, she exercised an undue influence over his judgment, or dictated his compositions. He accordingly set out with a determination of never consulting her, or yielding to her influence, and was always careful, when engaged in writing, that she should be ignorant of the subject which occupied his thoughts. His wife has been often heard to lament that want of sympathy and union of mind which is so desirable in married life. This peculiarity, however, in the husband so much increased, that in after years the most trifling proposition on her part was canvassed and discussed by every kind of argument. In the meantime he acquired strange peculiarities of habits. His love of order, or placing things in what he considered order or regularity, was remarkable. He was continually putting chairs, &c. in their places; and if articles of ladies' work or books were left upon a table, he would take an opportunity *unobserved* of putting them in order, generally spreading the work smooth, and putting the other articles in rows. He would steal into rooms belonging to other persons for the purpose of arranging the various articles. So much time did he consume in trifles, placing and replacing, and running from one room to another, that he was rarely dressed by dinner-time, and often apologised for dining in his dressing-gown, when it was well known that he had done nothing the whole morning but dress. And he would often take a walk in a winter's evening with a lanthorn, because he had not been able to get ready earlier in the day. He would run up and down the garden a certain number of times, rinsing his mouth with water, and spitting alternately on one side and then on the other in regular succession. He employed a good deal of time in rolling up little pieces of writing-paper which he used for cleaning his nose. In short his peculiarities were innumerable, but he concealed them as much as possible from the observation of his wife, whom he knew to be vexed at his habits, and to whom he always behaved with the most respectful and affectionate attention, although she could not influence him in the slightest degree. He would, however, occasionally break through these habits; as on Sundays, though he rose early for the purpose, he was always ready to perform service at a chapel a mile and a half distant from his house. It was a mystery to his intimate friends when and how he prepared these services. It did not at all surprise those who were best acquainted with his peculiarities, to hear that in a short time he became notoriously insane. He fancied his wife's affections were alienated from him, continually affirming that it was quite impossible she could have any regard for a person who had rendered himself so contemptible. He committed several acts of violence, argued vehemently in favour of suicide, and was shortly afterwards found drowned in a canal near his house.

It must not be omitted that this individual derived a predisposition to madness by hereditary transmission: his father had been insane.

Of Mania.—The phenomena of mania in its ordinary form are very distinguishable from those of monomania. The aspect, the voice, the gestures of the lunatic in the active state of maniacal derangement, form a contrast with the retired and morose habits of the sullen monomaniac. In cases, however, of mania, distinctively so termed, one impression often occupies the mind of the individual for the time being, and this is frequently some hallucination respecting his own person, some magnificent dream of self-importance and superiority. M. Pinel says, "I was frequently followed at the Bicêtre by a general, who said that he had just been fighting an important battle, and had left fifty thousand men dead on the field. At my side was a monarch who talked of nothing but his subjects and his provinces. In another place was the prophet Mahomet in person, denouncing vengeance in the name of the Almighty. A little further was a sovereign of the universe, who could with a breath annihilate the earth. Many of them seemed to be occupied by a multiplicity of objects, which were present to their imaginations. They gesticulated, declaimed, and vociferated incessantly, without appearing to see or hear any thing that passed. Others, under illusive influence, saw objects in forms and colours which they did not really possess. Under the influence of an illusion of that kind, was a maniac who mistook for a legion of devils every assemblage of people that he saw. Another maniac tore his clothes to tatters, and scattered the straw on which he lay, under the apprehension that they were heaps of twisted serpents."

Ordinary mania, or madness affecting the mind with a general disturbance of the intellectual faculties, is sometimes preceded by occasional fits of excitement and confusion, in which the understanding is hurried and disordered. But it differs from monomania in making its attacks for the most part suddenly and without any premonitory symptoms. An individual, after having undergone an unusual degree of mental and bodily exertion and fatigue, after a fit of intoxication, which in this country is one of the most ordinary of exciting causes of madness, after the excitement of violent passions or anxieties, after exposure to cold and the inclemencies of weather, passes sometimes a day or two in a state of feverish disorder and general uneasiness, and two or three restless nights. His mind is then found to be confused; he appears scarcely to know what he says, talks nonsense, repeats his words frequently, expresses his feelings with an absurd degree of warmth and enthusiasm, cries, laughs, utters rapid and confused sentences in a hurried and impetuous manner. "In the course of a few days, or sometimes at first, he is seized with violent agitations, expresses vague and continual apprehensions, is subject to fits of terror; he is in a state of constant excite-

ment and sleeplessness; he indicates the troubled state of his mind by unusual gestures, by singular appearances of the countenance, and by actions which cannot fail to strike in a forcible manner every observer. The various aspects which the symptoms of the disease assume at this period, have never been more graphically described than by M. Pinel. "The patient sometimes keeps his head elevated and his looks fixed on high; he speaks in a low voice, or utters cries and vociferations without any apparent motive; he walks to and fro, and sometimes arrests his steps as if excited by the sentiment of admiration, or wrapt up in profound reverie. Some insane persons display wild excesses of merriment, with immoderate bursts of laughter. Sometimes, also, as if nature delighted in contrasts, gloom and taciturnity prevail, with involuntary showers of tears, or the anguish of deep sorrow, with all the external signs of acute mental suffering. In certain cases a sudden reddening of the eyes and excessive loquacity give presage of a speedy explosion of violent madness, and the urgent necessity of a strict seclusion. One lunatic, after long intervals of calmness, spoke at first with volubility, he uttered frequent shouts of laughter, and then shed a torrent of tears; experience had taught the necessity of shutting him up immediately, for his paroxysms were at such times of the greatest violence. It is often observed that extatic visions in the night are the preludes to fits of maniacal devotion; and by enchanting dreams, or by the fancied apparition of a beloved object, it sometimes happens that erotic madness breaks out with violence, when it may either assume the character of a calm reverie, or display nothing but extreme confusion in the ideas and the entire subversion of reason."

When the disease has taken a firm hold on its unfortunate victim, it sometimes gives rise to all the internal effects, and displays all the external phenomena which the most intense feelings of human misery, resulting from the real calamities of life, may be imagined to produce. The maniac who becomes the subject of violent excitement "is seen in a state of extreme agitation, with his face flushed, his eyelids inflamed, and his eyes sparkling, his temples beating violently; he talks, cries, sings, grieves, gets into fits of rage by night and by day, and is incapable of taking rest. The melancholic, also, in extreme agitation, but wrapt up in himself, goes to seek in some quiet and dark recess a refuge from his panic terrors, from his gloomy and despairing thoughts; or the means of putting into execution his baneful designs. The insensible and stupid, incapable of any thing, remain unconscious of surrounding objects, and do not even exert themselves to satisfy their most urgent wants. At this period of madness there is a constant want of sleep: the patient often experiences a feeling of tension and of heat in the head, without, however, complaining of it." Sensibility to external impressions, as well as to all bodily changes, is so much lessened, that blisters, cauteries, as well as exposure to in-

tense cold, will sometimes produce but little expression of pain or distress.

4. *Of Incoherent Madness.*—A very peculiar and well characterised form of mental derangement is that of incoherent madness, or incoherency, in which the mind is occupied by a rapid succession of unconnected thoughts and evanescent emotions, and becomes entirely incapable of reflection, or even of distinct apprehension. Such cases are frequent, and are to be met with in every receptacle containing a considerable number of lunatics. Incoherent madness, or incoherency, is the most proper designation for this state of disease, as it describes the essential and characteristic feature. By Pinel the term *démence*, or dementia, has been adopted; and to this there would be no objection if it were not for the circumstance that the same term has been used by Esquirol and Georget with a different meaning, and that confusion would hence arise from an ambiguous designation. Under the term *démence*, the writers last mentioned describe that state approaching to fatuity or idiotism, which is the termination of protracted insanity, and in this sense the word is now commonly received. Since this is a morbid condition very distinguishable from that incoherency which is a primary and idiopathic form of mental derangement, each of these states of disease must have a particular epithet.

This form of madness is in some instances a primary affection; at least the tendency to incoherency displays itself very early in the progress of the case. The disease commences with great excitement; the patient is restless and unusually active; his manners are full of bustle and violence; his countenance flushed; he has sleepless nights; his thoughts follow each other with turbid rapidity; and his whole appearance strongly resembles that of a man of excitable temperament intoxicated with wine or spirituous liquors. In many cases there is no hallucination or erroneous impression on the mind that can be traced, but the violent and irrational activity of the patient is such as to require coercion. The succession of confused and imperfect ideas becomes after a time so rapid as to preclude distinct utterance. The association which connects images in the mind seems to be lost, or at least cannot be traced, and the thoughts appear to be single and insulated. Words and sentences are half pronounced; the voluntary movements are without design, and the effort to perform them is incomplete; it is impossible to fix the attention of the patient sufficiently for obtaining a reply to the shortest question; he becomes almost insensible to the existence of external objects, talks incessantly, or repeats the same word or half sentence over to himself; he takes his food, when it is offered to him, by hasty snatches, and swallows it greedily, or spits it out again in order to continue his unmeaning jargon. After this state of excitement has continued for some time it gradually subsides, and the disease either continues with mitigated violence, but still with the same form of incoherency and want of connection in the course of thoughts

and feelings, or the expressions gradually appear to be more connected, the patient becomes capable of sleep, and a slow progress towards the restoration of the reasoning faculty is perceptible. The writer of the present article has witnessed several instances of complete recovery of the mental powers after the existence, during many weeks and even months, of maniacal phenomena answering to the above description; and every physician who has had opportunities of inspecting lunatic asylums must have observed many cases in which the state of incoherency has terminated in recovery, and others in which it has become chronic and permanent.

The following case described by Pinel is a well-marked instance of the morbid state now under consideration, and it will be sufficient to prove that the affection termed by that writer *démence* is precisely what we have designated as incoherent madness.

"An ardent but ill-informed patriot, and one of the warmest partisans of the celebrated Danton, was present at the sitting of the legislative body, when the writ of accusation was pronounced against that deputy. He withdrew in consternation and despair, shut himself up in his own apartment for several days, and surrendered himself to the influence of the most gloomy ideas. 'What! Danton a traitor!' he repeated without ceasing; 'then is there no man to be trusted; the republic is lost!' His appetite and sleep forsook him. Complete insanity ensued. Having undergone the usual treatment at the *ci-devant* Hôtel Dieu, he was removed to the Bicêtre. He passed several months in the infirmary of this hospital in a state of tranquil reverie, uttering incessantly half-expressed and unconnected sentences. He talked alternately of daggers, sabres, dismantled vessels, green meadows, his wife, his hat. He never thought of eating but when food was actually put into his mouth; and in respect to his functions he was almost levelled with an automaton."

The chronic form of incoherence presents similar phenomena, but in a milder degree. Patients in this last state have intervals of rest; they sleep, and have periods of tranquillity during their waking hours, but seldom or never display coherence and arrangement in their ideas, or make any approach towards a sane and vigorous use of the reasoning powers. Neither have they any appearance of melancholy or abstraction, but they are capable of being momentarily excited by objects which impress their senses and by the scenes around them, though their impressions are transitory and evanescent. They talk to themselves or to others for a long time in phrases scarcely connected by any perceptible link, and in which there is rarely a glimpse of meaning; and if any association can be traced in their thoughts, it is of the most trivial kind, and depending on a word or some sensible object which for a moment attracts their attention. They will sometimes repeat the same word or half sentence many times, but soon forget it.

The disease which we have now described

under the designation of incoherent insanity has been by some writers identified with dementia, or the first stage of fatuity. It is, however, a particular form of mental disease, assuming its peculiar character from the first, and displaying phenomena very different from those of dementia, though, like other forms of madness, it is liable, when long protracted, to pass eventually into fatuity. The writer of this article has seen in private practice and in hospitals several well-marked cases of incoherent madness in the acute form, which ran their course and terminated in recovery without passing into the chronic stage. Of the chronic form, which approaches most nearly to dementia, but may yet be distinguished from that state of disease in its ordinary appearances, some illustrative cases have been pointed out to him in the Lunatic Asylum at Fishponds, near Bristol, by Dr. Bompas, the humane and intelligent conductor of that establishment. Two of these occur in brothers, whose symptoms are very similar, though those of one are more strongly marked than of the other. Although the former of these individuals has been in confinement for many years, his countenance does not display the well-marked aspect of dementia, of which M. Esquirol has given so excellent a delineation. If questioned, he replies with an intelligent look, but in words quite beside the subject, and chatters about a hundred unconnected things in the course of a few minutes. If you repeat the question, it only increases his volubility without apparently drawing his attention a whit more nearly to the subject of inquiry.

5. *Observations on the state of the faculties in madness.*—It has been a question frequently agitated among medical writers, in what precise changes in the organic operations of the brain, as well as in the mental processes which result from these operations, madness consists. The present is not a suitable opportunity for entering into a full discussion of this subject. In a practical point of view, all that is requisite will be obtained by a brief inquiry into the actual condition of the intellectual faculties in insane persons.

It may be observed that consciousness generally remains unimpaired in lunatics, though its exercise, in some cases of madness with hallucination, is connected with singular phenomena. The patient is conscious of his sensations, but he sometimes expresses himself as if his notion of personal identity were strangely confused. He talks and reasons about his feelings as if they were those of another individual. These are by no means frequent cases, and in general lunatics have a distinct perception of their personal identity, and refer their sensations and ideas correctly to themselves.

Sensation likewise remains unimpaired in the insane: the organs of sense at least are not the seats of disease, nor are those processes in the nervous structure on which sensation depends in a deranged state. The sensations produced by light and sound are sometimes morbidly acute, from temporary affection of

the organs of sight and hearing, but this is accidental, and by no means a circumstance characteristic of madness. The effects of cold and other painful impressions are in some instances disregarded by lunatics, but this seems to be merely a result of intense excitement of the mind and its direction to other feelings and operations. Such cases are not so frequent as they are supposed to be, and in general lunatics are sensitive of external impressions.

Perception of external objects is generally unimpaired, but in some cases it is strangely affected and perverted by the morbid impressions on the mind, and by the influence of the prevailing hallucinations.

Maniacal hallucinations are of two kinds. Dr. Cullen has remarked that "*there is sometimes a false perception* or imagination of things present that are not; but this is not a constant nor even a frequent attendant of the disease. The false judgment is of relations long before laid up in the memory."* This means that the hallucination seldom refers to the scene actually present, but to the impressions of memory. When, however, the maniacal reverie becomes very intense, it produces hallucinations or false impressions which represent unreal objects as actually present. Even in this case it does not appear that perception is impaired. Some particular phantasms, the creations of reverie, are presented to the mind in colours so vivid as to produce an effect similar to that of actual perception; the patient in other respects makes no mistakes with regard to place or time; his perceptions of external objects are correct and uniform whenever his attention is directed to perceptible things; but he is so intent upon his reverie, that for the most part he totally neglects them; his fancy becomes so intense in its operation as to carry him away from the influence of his external perceptions, and to environ him with visions of unreal scenes.

We have often seen a lunatic under this form of disease walk up and down a frequented place, sufficiently alive to external objects to avoid falling in the way of horses and carriages, or running against foot passengers, but so intent upon the scene presented by his excited imagination as to be busily employed in issuing commands to troops of which he imagined himself to be the general, and in directing them to enfilade to the right and left, and perform a variety of evolutions. All this he performed with a voice and gesture that were perfectly natural and consistent with reality. To this modification of madness belong those maniacal hallucinations termed by some writers *idolomania* or *dæmonomania*, in which the lunatic fancies that he sees and holds converse with imaginary beings. The conception of the mind is so vivid and intense, that it withdraws consciousness entirely from the sensations excited by surrounding objects, which nevertheless exist, and occasionally under particular circumstances give rise to perception. Maniacal hallucinations have, however, a much

firmer hold on the belief in some cases of madness than the strongest evidence afforded by perception, and hence the futility of those projects which are occasionally suggested for surprising lunatics into a conviction of their false judgments. An insane female confined in an asylum had a firm persuasion that her husband was dead. When he came to visit her, she asserted that it was the devil who had assumed his form. Her recollection and perception had remained unimpaired, but the insane hallucinations overcame their evidence and held possession of her mind.

The power of reasoning or judgment does not appear to be so much impaired in madness as the disposition to exercise it on certain subjects. Often there is a manifest unwillingness to admit any evidence unfavourable to the false notions impressed upon the mind, while great ingenuity is displayed in finding arguments which may tend to make it apparently more reasonable. A case illustrative of this remark has been already mentioned.

In many instances of madness it would appear that the characteristic feature of the disease is a morbid inclination to indulge in reverie, and to yield the judgment and all the faculties to its controul. The impressions of reverie are so modified by disease as no longer to be distinguishable from those of memory or active reflection. We may venture to say that this observation will go far towards explaining the mental phenomena of the disease.

6. *Disorders in the state of the physical functions attendant upon madness.*—The phenomena of madness which attract most observation, and which indeed characterize the disease, are those which depend upon the disordered state of the cerebral functions; but other processes in the living body are likewise in a state of derangement. There is in most cases of insanity, besides the morbid condition of the brain and nervous system, more or less of disturbance in the physical functions; the secretions, excretions, appetite, and digestive processes are frequently disordered. Medical writers have differed in opinion as to the relation which these affections bear to the cause of insanity. Pinel has stated it to be the result of his inquiries that the primary seat of mental alienation is generally in the region of the stomach and intestines, and that from that centre it propagates itself, as it were, by irradiation, and deranges the understanding. Others have looked upon the disorders in the functions of the viscera as merely contingent results of a primary disease, seated in or immediately affecting the brain.

Whichever of these opinions may be correct, the general, or at least the frequent co-existence of disorder in the physical functions with that affection of the brain from which the deranged state of the mind immediately results is an indisputable fact.

The physical functions are differently affected in different forms of madness. In disorders of slow and gradual accession, and especially in those cases in which the mind is melan-

* First Lines, ¶ 1558.

choly and depressed, a torpid state of the vital and natural functions for the most part prevails; the circulation is languid; the pulse weak and generally slow; the extremities cold; the skin cold and clammy; most of the secretions are defective; the bowels are torpid, and sometimes obstinately constipated and flatulent, requiring strong doses of aperient medicine. The appetite is defective; digestion is impaired; sometimes there is a constant loathing of food, which, if the patient were not obliged to eat, would induce him to starve himself, and it is often extremely difficult to persuade persons in this state to swallow nutriment sufficient for the preservation of life. Emaciation and loss of strength inevitably result from these circumstances, but they are sometimes not so striking as any person would anticipate.

Attacks of maniacal disease, which break out suddenly with great excitement of the passions, with general disturbance of the intellectual faculties, or with incoherence, are almost always accompanied by symptoms of fever or pyrexia more or less acute. The pulse is rapid, often full, and beating with disproportioned strength in the carotid and temporal arteries; the skin is hot and the tongue white; there is thirst; with loss of appetite, headach, sleeplessness, and great irritability; the secretions are deficient; the urine is high-coloured and scanty, and the bowels are constipated. The face is often flushed; the eyes are glossy and suffused; the conjunctiva is injected with blood, and the pupils are contracted. The patient sometimes complains of pain in the forehead and temples, with a sense of weight upon the head, or of constriction, as if the scalp were tightly drawn. It has been observed that in some instances persons who had previously suffered severely from headach have ceased to complain of it when madness has supervened, and that it has returned when such patients have become convalescent. Want of rest is often a troublesome and distressing symptom. Many patients pass whole nights without closing their eyes, or when they obtain sleep, it is short and agitated. In other instances a few hours of sound sleep are the prelude to a paroxysm of renewed excitement, the maniacal symptoms breaking out on waking with increased violence.

All the symptoms which refer themselves in a perceptible manner to the head are liable to undergo occasional exacerbations during the continuance of madness. Increased heat of the scalp, redness of the eyes, fulness and strong pulsation of the carotid and temporal arteries, want of sleep and consequent irritability of the temper and feelings, indicate and precede or accompany renewed periods of violence in the symptoms of mental derangement.

In many instances of maniacal disease there is much disturbance in the functions of the intestinal canal. This observation has been made more particularly in persons whose general health has been previously much neglected; in the inmates of some lunatic asylums; in individuals of the lower class, who have been subjected to hardships and unwholesome diet,

as well as to cold and a damp unwholesome atmosphere; in cases in which the disease has followed excesses of various kinds, or confinement on ship-board, with the use of salt provisions. In many instances of this description it has been found that the bowels had been long in a confined and torpid state. In those instances in which it is stated that the bowels are open and even more loose than natural, it often appears on further examination that a long-continued torpor and constipation have given way to diarrhoea; the abdomen, which had previously been swelled with indurated matter, has become more distended than before, flatulence being added to the load of solid contents but partially discharged. The evacuations are thin and watery, or contain mucus mixed with vitiated bile and recent aliment in an undigested state. Sharp and transient pains are experienced in various parts of the abdomen, which is often tender on pressure; at length, in very neglected cases, dysentery supervenes and brings on extreme emaciation. The tongue is often red or covered with a brown fur, and the mouth and fauces with a viscid mucus, which, together with saliva, the patient spits out in all directions. There is great thirst and a peculiar fetor of the breath, which extends to the whole person. The appetite is depraved; in many cases the patient has an aversion to all food; in other instances he has a keen and voracious desire for it, and greedily devours without selection every thing eatable that falls in his way. The skin is cold; there is a remarkable coldness of the extremities, resulting from the damp state of the skin and a want of energy in the circulation through the extreme vessels. In some cases of long duration there are papular or scaly eruptions; and in exhausted and debilitated subjects, furunculi appear in various parts of the body, which are much disposed to slough.

Cases of madness, coming on with some degree of rapidity, are often preceded and sometimes accompanied or followed by suppressions of natural or customary discharges, by the disappearance of external diseases, or the cure or suspension of internal complaints. The relation which these changes bear to madness as causes or results may be different in different cases; they are connected circumstances of that disease. The catamenia, if not suppressed previously to the manifestation of cerebral disorder, soon become scanty, or cease entirely after its actual appearance. Lochiæ and other analogous effluxes are suppressed; ulcers, which had become habitual and had long discharged, are dried up; chronic eruptions generally disappear, or are materially lessened; symptoms of pulmonary phthisis in various stages cease or become mitigated in a remarkable degree. On the decline of maniacal disease, it is often found that the return of such discharges, or the revival of suspended trains of morbid symptoms such as we have described, is the harbinger of restoration to a sound state of mind, though not to complete bodily health.

SECT. III.—*Of the duration of insanity, and of the modes of its termination.*

The duration of insanity is various, and admits of no general estimate. In some instances this disease has subsided in the course of a few days after its commencement; in others it continues for many years. M. Esquirol has remarked that it is not uncommon to meet with inmates of lunatic asylums who have been twenty, thirty, or even forty years in confinement. The same observations must have occurred to every person who has been in the habit of visiting such establishments.

Insanity has three different terminations:—first, in recovery; secondly, in a state of fatuity, or of chronic and permanent failure or obliteration of the mental faculties; thirdly, in death. The last is generally the contingent result of some of those disorders in the physical functions of the body to which the insane are especially liable. We shall allot a separate consideration to the circumstances connected with each of these events of insanity.

1. *Of recoveries from insanity.*—Recovery from madness sometimes takes place suddenly, but more frequently it is gradual, and preceded by several periods of mitigation in the intensity of disease, and often by lucid intervals.

The prospect of recovery is much greater in young persons than in those of advanced years, and it diminishes, other circumstances being equal, with the patient's age. M. Esquirol has observed that few lunatics are cured after the sixtieth year. It must, however, be taken into the account that few comparatively are for the first time attacked by madness after that period of life.

The curability of madness, or, to speak more correctly, the proportion of maniacal cases which terminate in recovery, is likewise subject to great variation from circumstances which refer to the nature of the disease, its occasional complication with other maladies, the sex and constitution of the patient, the mode of treatment to which he is subjected, and the causes which have given rise to his disorder; and hence any general calculations on this subject are matters rather of curiosity than of practical value. One remark, however, may be of use, as it may encourage medical practitioners in their efforts to remove or mitigate the disease. Of cases which present no peculiarly unfavourable combinations, a much larger proportion terminate in recovery than is generally supposed, or than any person could be led to believe from the inspection of reports from hospitals. In these reports it generally happens that a great number of inveterate cases, and of such as are incurable from their conjunction with other diseases dangerous to life, and indicating changes in the organic condition of the brain, are blended with those of simple insanity in the general averages.

M. Esquirol has endeavoured, by comparing the reports of several extensive hospitals in France and England, to throw some light on the curability of madness, or on the proportion of recoveries. The following table presents some facts which are of great interest.

<i>Table of recoveries from madness.</i>			Admissions.	Recoveries.
<i>In England.</i>				
In Bethlehem Hospital from 1748 to 1794	8874	2557
" " " in 1813	422	204
In St Luke's from 1751 to 1801	6458	2811
In York Asylum	599	286
In the Retreat, near York from 1801 to 1814	163	60
	Totals ..		16516	5918
<i>In France.</i>				
Charenton from Nov. 22, 1798 to 1800, 22 July 1803	97	33
Salpêtrière from 1801 to 1805	499	161
" from 1804 to 1813	1002	407
" from 1806 to 1807	2005	1218
" from 1812 to 1814	531	286
" from 1801 to 1813	891	413
In M. Esquirol's private establishment,	from 1801 to 1813	335	173
	Totals ..		5360	2691

From the data contained in this table, M. Esquirol concludes, "first, that the absolute number of recoveries from madness is about one in three; secondly, that the number of recoveries varies from one in four to one in two, or to one-half of the number of persons affected: this difference depends upon particular circumstances of locality, on the nature of the cases, and of the treatment pursued: thirdly, that cures are more numerous in France than in England." He adds that they are much more rare in Germany and in Prussia.

A much more extensive collection of reports from various lunatic asylums, both public and private, in England, France, and other countries, has been made by Dr. Burrows, who has constructed from these materials a table exhibiting the proportion of recoveries. The evidence afforded by such collections is very much confused, and in many instances rendered wholly inconclusive from the variety which exists in the regulation of different establishments as to the nature of the cases admissible into them, and the time during which the patients admitted are kept. For instance, the hospitals of Bethlehem and St. Luke impose certain exclusions elsewhere unknown. They reject all patients who have been more than twelve months insane; those affected by paralysis, however

slight, and by epilepsy or convulsive fits; idiots, the aged and infirm; those discharged uncured from other hospitals: there are likewise other exclusions besides those above mentioned, and all persons who have not recovered at the expiration of one year are dismissed. Yet, on comparing the reports of these hospitals with those of other institutions, the regulations of which are less favourable to a high proportion of cures, and where no selection or exclusion exists, we do not find, as Dr. Burrows remarks, the relative number of recoveries to be so great as might be expected. It is indeed surprising to find that the reports of Bethlem Hospital, of a century and a half ago, give a greater proportion of cures than those of many years preceding 1817, when an improvement took place in the arrangements of that establishment. Dr. Burrows remarks on the authority of Stow, who derived his information from Dr. Tyson, physician to Bethlem Hospital, that "from 1684 to 1703, 1294 patients were admitted, of whom 890 were cured, which is a proportion of two in three. But from 1784 to 1794, 1664 patients were admitted, of whom 574, or rather more than one in three, recovered." It is probable that there were circumstances in the former arrangements which, if they were known, would explain this difference. On the whole, the results of Dr. Burrows' inquiries are much more favourable to British hospitals than those of M. Esquirol. It appears, indeed, from his statements that the proportions of recoveries in England are greater than those obtained in France, Germany, and, *à fortiori*, in any other country in Europe. This may be in some degree judged of by comparing the following statements, taken during late years, with those previously given from M. Esquirol's collections.

In Stafford Asylum, from 1818 to 1828, admissions 1000; cured 429; or about 43 in 100.

In Lancaster County Asylum, from 1817 to 1825, admissions 812; cured 322; or about 39 in 100.

In Wakefield County Asylum for the West Riding of Yorkshire, from 1819 to 1826, admissions 917; cured 384; or about 42 in 100.

From these statements it clearly appears that M. Esquirol's computation of recoveries is much below what really takes place under favourable circumstances. The results are so different under different circumstances, that no general average can be of much value in a practical point of view.

Another inquiry, which admits of a more satisfactory elucidation, and which leads to results very interesting in their relation to prognosis, refers to the period of the disease during which recovery is chiefly to be expected. Some facts, tending to illustrate this question, were contained in a memoir presented by M. Pinel to the French Institute in 1800. It appeared from this memoir that the greatest number of recoveries from madness take place in the first month of its duration, the recoveries during the first being compared with those of succeeding months. The mean time for the

duration of the disease, in cases terminating favourably, was fixed in the same document at from five to six months. This result was deduced from a selection of cases from which the author excluded all those which had been under previous treatment, as well as cases of long duration. A longer term is assigned to this disease, in cases terminating in recovery, by Mr. Tuke in his account of the Retreat at York; and M. Esquirol, whose accuracy of research in subjects of this nature gives to his authority the highest value, confirms the opinion of Mr. Tuke. He has drawn this conclusion from a statement of the cases admitted into the Salpêtrière during ten years, as shewn by the following table.

Table of recoveries at the Salpêtrière during ten years.

Admissions.	1804.	1805.	1806.	1807.	1808.	1809.	1810.	1811.	1812.	1813.	1814.	Totals of Cures.

2005												1218

It seems that the report on which this table was founded, extended from the year 1804 to 1813; 2804 female lunatics were admitted during this interval, of whom 795 were considered as incurable, on account of their advanced age, or because they were idiotic, epileptic, or paralytic subjects. The remaining

2005 were put under treatment without regard to the duration or peculiar character of their disease. Out of this number, 604 were cured during the first year, 497 in the second, 86 in the third, and 41 in the seven succeeding years. From these data M. Esquirol draws the following conclusions: first, that the greatest number of recoveries are obtained in the two first years; secondly, that the mean duration of cases that are cured is somewhat short of one year; thirdly, that after the third year the probability of cure is scarcely more than one in thirty. There are, nevertheless, examples which prove that we ought never to despair of the recovery of lunatics. M. Pinel, from Baumes, cites the case of a lady who passed twenty-five years in a state of lunacy, within the knowledge of the whole country where she lived, and who suddenly recovered her reason. "I have seen," says the same writer, "a girl who from the age of ten years was in a state of dementia, with suppression of the catamenia. One day, on rising from bed, she ran and embraced her mother, exclaiming, 'Mamma! I am well!' The catamenia had just flowed spontaneously, and her reason was immediately restored. Such facts are rare, but they serve to prove that from the duration of the disease alone there is no reason to despair altogether of recovery." A few instances of the same kind have occurred in several lunatic houses or public hospitals, from the superintendents of which the writer of this article has obtained information respecting them.

From another table published by M. Esquirol, it appears that, out of 269 maniacal patients, 27 were cured in the first month of their illness, 34 in the second, 18 in the third, 30 in the fourth, 24 in the fifth, 20 in the sixth, 20 in the seventh, 19 in the eighth, 12 in the ninth, 13 in the tenth, 23 after the first year, and 18 after two years. This is perhaps an attempt at a greater degree of accuracy in calculation than is, from the nature of circumstances, attainable. The same writer has made a remark in illustration of the greater proportion of recoveries observed in the early period of madness, which is worthy of attention. He says, "I have constantly observed that in the course of the first month from the commencement of the disease a very marked remission takes place. About that period the maniacal excitement, which had previously run its course as an acute disorder, seems to have reached its termination as such, and it is then that it passes into a chronic state, the crisis having been incomplete. This remission, which I have watched with the greatest accuracy, must be attributed to the complaints which are complicated with madness at its commencement." The author implies, though he does not clearly express himself, that the natural termination of the disease, when unimpeded by complication with other maladies, or by more or less of organic lesion in the brain, is in the very early stage.

Recoveries from madness are in many instances complete. There are numerous persons who have been insane for six or twelve months,

or during a longer period, and have afterwards entirely recovered the vigour of their intellectual faculties, so as to be capable of as great and effective mental exertions as previously to the attack. Others, and perhaps these are the majority, are curable only to a certain point. These persons remain, as M. Esquirol has observed, in such a state of susceptibility that the slightest causes give rise to relapses, and they only preserve their sanity by continuing to live in a house where no mental agitation or inquietude, no unfortunate contingency is likely to fall to their lot, and throw them back into their former state. There are other individuals whose faculties have sustained such a shock that they are never capable of returning to the sphere which they had held in society. They are perfectly rational, but have not sufficient mental capacity to become again military officers, to conduct commercial affairs, or to fulfil the duties belonging to their appointments. Such cases may be about one-tenth in the number of recoveries.

Convalescents are as subject to relapse as those who are advancing towards recovery from other diseases. But lunatics are in many instances likewise prone to a recurrence of the disease after it has been entirely removed, or at least after its manifestations have long ceased to be observed. The same observation may be applied to other disorders of the nervous system. It would seem that one attack of disease has in these cases left the patient with a stronger predisposition than he formerly had to the complaint, whatever it may have been, and that the morbid tendency is strengthened after every renewed incursion. The most trifling circumstances have in these instances sufficient influence to produce the morbid condition of the brain and of the mind. At length the patient is scarcely ever in a lucid state; the intervals lessen in duration, and become more and more imperfect in degree, until disease finally becomes in a great measure permanent.

The proportion of cases in which madness is recurrent has been overrated. According to M. Pinel, in 71 cases out of 444 recoveries relapse took place, or, rather, the disease was in those instances recurrent. This gives somewhat less than one-sixth of the whole number as recurrent; but the same writer allowed that out of the 71 cases 20 patients had previously relapsed, or had undergone several attacks, 16 had left the hospital at too early a period, 10 came afterwards under treatment and recovered without relapse, 14 had given themselves up to grief and intemperance, and several others were under circumstances unfavourable to continuance in health. M. Esquirol published a report of 2804 recoveries, in which number only 292 recoveries of disease took place, that is, a little more than one-tenth. M. Desportes, however, has stated that, in 1821, 52 recurrent cases were recognized at the Bicêtre, out of 311 admissions, that is, about 17 in a hundred; at the Salpêtrière in 454 admissions there were 66 relapses, about 15 in a hundred, or one-seventh. But in the proportion of recurrent

cases indicated by this last report, it is probable that there were, as M. Georget has well observed, many cases which had been discharged in a state of incomplete recovery, as well as a considerable number of drunkards, who come habitually every year to spend a few weeks in the Bicêtre or the Salpêtrière, having been picked up in the streets in a state of intoxication.

In all instances we may consider it as certain that the improbability of recurrence increases with the length of the interval of time during which the patient has existed without manifesting signs of renewed disease, and that it is also greater in proportion to the completeness of the recovery. When the energy of mind is fully restored, relapse is much less to be feared than when it remains weak and excitable.

Second termination.—Fatuity—Dementia—Amentia.—The ultimate tendency of madness when protracted, and the state to which insane persons, if they do not recover, are in general sooner or later reduced, is that of fatuity. The fatuity which constitutes the last stage of mental derangement differs in its phenomena from congenital idiotism. It has more resemblance to the imbecility of extreme old age, but from this last affection, which we shall describe at the conclusion of the present treatise, it is distinguishable and in many instances very different. For the sake of greater precision we shall divide maniacal fatuity into two grades or stages. The first is that state which Esquirol and Georget have named *démence* or dementia, a term which is established by the authority of these writers, and has been received into general use: the second stage of fatuity, which is the last period of mental decay, and presents an almost entire obliteration of the faculties, may be properly distinguished by the term *amentia*.

1. *Dementia.*—The approach of dementia, or the first period of fatuity, is indicated by a comparative state of calmness succeeding to the previous excitement of the maniacal period. It is not the calmness of returning reason, but the result of mental activity worn out, the subsidence or obliteration of the affections or moral feelings, and the decay even of physical sensibility. It has been well remarked by M. Georget that the characteristic of dementia is a forgetfulness of the past, with a total indifference as to the present and future. Demented persons are generally quiet and inactive; they take little notice of persons or external things, without appearing to be occupied by any internal emotion or train of thought. They often, however, smile or laugh without any apparent reason, or sing, or pronounce, as if accidentally, single words or sentences. Some remain for days or weeks without uttering a word, or betraying by look or gesture the least consciousness of external impressions. Such impressions, however, are sometimes afterwards discovered to have been not entirely unobserved. Many appear, by their looks or replies to questions, to know and remember their friends or relatives, but scarcely display signs of emotion or sensibility on being

visited by them. Not a few even in this state are capable of being employed in mechanical occupations. Females knit or sew, or perform any work with their hands to which they had been previously habituated; and men draw, or write letters or sentences, in which, however, their imbecility is generally conspicuous. Some patients have occasional periods of greater excitement, in which the symptoms of a more active state of madness resume their prevalence. In other instances mere physical activity displays itself at intervals in peculiar ways, as by running, jumping, or walking round continually in a circle or determinate figure.

The physical health of patients thus affected is in general tolerably good; they are often fat, have good appetites, digest their food, sleep well, and if in the previous stages of the disease they had been emaciated, they often recover their natural degree of plumpness on the approach of dementia. Hence the return of physical health without a corresponding improvement in the state of the mental faculties, is, as it has been remarked by the writer last cited, an unfavourable prognostic in cases of maniacal disease.

There are, however, some rare cases of recovery from this first stage of fatuity. Pinel informs us that many, especially young persons, who had remained in the Bicêtre several years or months in a state of absolute idiotism, have been attacked by a paroxysm of acute mania of twenty, or five-and-twenty, or thirty days' continuance. "Such paroxysms," he adds, "apparently from a re-action of the system, are in many instances succeeded by perfect rationality." The same result has been observed on the restoration of demented persons or of maniacs in the advanced stage of insanity after severe attacks of fever of that kind which is usually attended with delirium. Such attacks are often fatal to lunatics; but of those who recover them not a few are subsequently restored to the possession of their faculties.

These instances of restoration from fatuity take place only after the first stage. When the disease has passed into complete amentia, it is altogether hopeless.

2. *Amentia.*—Scarcely any exhibition of human suffering can be more deeply affecting than the aspect of a group of lunatics reduced to the last stage of fatuity, and those who have never witnessed such a spectacle can hardly imagine so abject a state of mental degradation. In a group of this description an individual may be seen always standing erect and immovable, with his head and neck bent almost at right angles to his trunk, his eyes fixed upon the ground, never turning them round, or appearing by any movement or gesture to be conscious of external impressions or even of his own existence. Another sits on a rocking chair, which she agitates too and fro, and throws her limbs into the most uncouth positions, at the same time chaunting or yelling a dissonant song, only capable of expressing a total inanity of ideas and feelings.

Many sit constantly still, with their chins resting on their breasts, their eyes and mouth half open, unconscious of hunger or thirst, and almost destitute of the feelings which belong to merely physical life; they would never lie down or rise were they not placed in bed and again raised by their attendants. A great proportion of the patients who are reduced to this degree of fatuity are found to have lost the use of their limbs in a greater or less degree by partial or general paralysis.

From such a state it is scarcely imaginable that recovery ever took place, but patients in the last stage of fatuity often linger for many years. Their state, however, is not always uniform: some of them have comparatively lucid intervals, at which nature seems to make an effort to light up the mind and recall lost impressions and ideas. A patient has often been observed by the writer of this article, who sits all day in a wooden elbowed chair, with his chin hanging over his breast, appearing hardly conscious of existence and unable to assist himself in the calls of nature, who would not eat if food were not actually put into his mouth. He has been for several years in the same state, except that he occasionally appears to rouse himself, and for a short time to recover an unusual degree of animation. At such periods he will sometimes read a chapter in the Bible with a clear voice and a distinct and intelligible articulation.

3. *Of the termination of madness in death.*
—Madness is not to be reckoned among the diseases which are very dangerous to life. The state of the brain on which it depends, though incompatible with the continuance in a sound state of those functions on which the mental operations are associated, is yet such as to carry on other processes, dependent on the brain, which are subservient to physical existence.

This conclusion is established in a most convincing manner by the duration of insanity, and the cases even of longevity which occur among lunatics. We are informed by M. Desportes that among the lunatics at the Bicêtre in the beginning of the year 1822, one had been lodged there fifty-six years, 3 upwards of forty years, 21 more than thirty years, 50 upwards of twenty years, 157 more than ten years. At the Salpêtrière the entry of patients dated, 7 cases from fifty to fifty-seven years, 11 from fifty to sixty, 17 from forty to fifty.

The morbid state of the brain is, however, liable to increase beyond the limit above adverted to, and then the usual phenomena dependent on severe cerebral disease are manifested. It is well known that lunatics are subject in a much greater proportion than other persons to apoplexy, palsy, epilepsy, and all the trains of symptoms depending on different degrees or modifications of cerebral congestion.

Another mode by which madness brings on a fatal termination is by the exhaustion arising from continued excitement. There are many cases of maniacal disease in which the ceaseless excitement of the feelings, the constant hurry of mind and agitation of body, the total

want of rest and sleep, and the febrile disturbance of the system which frequently ushers in the attack of madness, and is always a prominent feature in cases of this description, bring on a very marked reduction of strength as well as of flesh: the degree of emaciation is sometimes extreme. Generally this state of excitement gradually abates, or the means adopted to lessen it and tranquillize the system are attended with success; but this is not uniformly the case, and some maniacs die completely worn out and exhausted. It is in part owing to this cause that the mortality among lunatics is more considerable during the two first years from the period of their attack than in the succeeding years, a fact which appears to be established by the calculations of M. Esquirol. In the Salpêtrière the number of deaths is even much greater in the first year than in the second. Of 790 lunatics who died in that hospital between the years 1804 and 1814, it appears that 382 died in the first year from their admission, 227 in the second year, and 181 during the seven succeeding years.

Many lunatics are carried off by diseases of the abdominal and thoracic viscera, which are complicated with madness. Pathology does not enable us to explain the connexion between organic diseases of the lungs or bowels and disordered action of the encéphalon, and hence many have been inclined to regard the combinations of morbid states to which we now advert as accidental. They are perhaps too numerous to be attributed to chance. The combination of madness, as well as of some other diseases of the brain and nervous system, with diseased states of the liver and of the intestinal canal, was pointed out some years since by the writer of this article. The conjunction of insanity with pulmonary phthisis is a fact established beyond doubt by the observations of M. Esquirol, who remarks that phthisis often precedes the appearance of melancholia, or accompanies it. The disease of the lungs is in these instances latent; the patients lose their strength, become emaciated and suffer under slow fever, sometimes attended with cough and diarrhœa; the phenomena of madness rather increase than abate under these circumstances, and continue until death. On the examination of the body, the lungs are found tuberculated or affected by melanosis.

Diseases of the heart are not unfrequently complicated with madness. We are assured by M. Foville, that, of the bodies of lunatics which he examined after death during three years, five out of six displayed some organic disease either of the heart or the great vessels. This was very frequently hypertrophy of the heart. These morbid changes, however, are probably, as M. Foville has observed, more frequently results of the continued agitation, the violent efforts and cries, which in such patients bring on diseases in the thoracic organs, than predisposing causes of cerebral disorder.

Diseases of the intestinal canal, whether they exist or not at the onset of the maniacal

attack, are subsequently among the frequent causes of death. A state of obstinate constipation often continues for a long time, attended by its usual accompaniments. It gives way, and is followed by or alternates with diarrhœa, which wastes the strength of the patient and terminates in a fatal dysentery. When the body is examined, the intestines are found sometimes distended and loaded with indurated matter, at others empty and pale, with disease of the mucous coat, discoloured and abraded patches or ulceration, and gangrenous spots.

In protracted cases death either results from increase in the disease of the brain, which up to a certain degree had only subverted the operations of that organ subservient to the mental function, and at length becomes incompatible with the merely physical functions of the same viscus; or it is the result of accidental disorders, which, owing to the peculiar state of the brain and other organs in lunatics, are more than usually fatal.

Fatuity or inveterate lunacy becomes complicated with paralysis. M. Esquirol says that of the number of persons who die in a state of lunacy, one half are paralytics. This paralysis of the demented is a peculiar affection, for we are not now referring to hemiplegia, attacks of which are liable to occur at all periods of madness, either ushered in by apoplexy or without it, and which frequently carry off maniacal patients. The general paralysis to which lunatics in the advanced stage are most subject shews itself first in the muscles of articulation; patients have some difficulty and imperfection in speech, which is in the beginning so trifling as to escape those whose attention is not particularly directed to the circumstance. The muscles of the limbs and trunk become subsequently affected; the patient walks with a tottering or shuffling gait, and his trunk is bent forward; his hands shake; his limbs become emaciated and feeble; sometimes he bends towards one side, and at length passes his time in a sitting posture, and bent forward, or takes to his bed, when the sphincters gradually lose their power, sloughs take place about the back, the sacrum, and elbows, followed by gangrene and death.

Many lunatics in the advanced stage labour under a degree of cachexia bordering on scurvy. The skin is beset with scaly or papular eruptions, or discoloured in patches; furunculi appear in different parts of the body, which are much disposed to become sloughy; the gums become red and sore, and bleed; the surface of the body is cold with a clammy perspiration; diarrhœa, and abdominal pains accompany these symptoms; the patient apparently suffers under defective nutrition and a gradual decay of physical life, and dies in a state of extreme emaciation or marasmus.

The preceding are perhaps the natural sequelæ of the diseases under which lunatics suffer in connexion with their original complaint. A great number, however, are carried off by disorders which may be considered as accidental, but to which the condition of body in patients of this description ren-

ders them more than other individuals liable. Fevers which assume more or less of the typhoid character, severe catarrhs, and pulmonary affections, are the most frequent of them. It will be supposed that fevers which affect the brain are fatal to lunatics, and such is the fact in a very marked degree.

The diagnosis of accidental diseases in lunatics presents, as M. Georget has well observed, remarkable difficulties. Some patients of this description are continually making unfounded complaints, deceived by their erroneous or fancied sensations. On the other hand, many lunatics labour under very severe affections without revealing them by any expression, either because these affections are latent and do not occasion suffering, or because the disturbed state of their minds does not allow their sensations to reach the centre of perception. In this last relation the medical treatment of lunatics is much more obscure and difficult than that of young children, because the latter are conscious of their ailments, and express them by their cries. "When we observe a lunatic, who had previously been agitated and furious, become morose and taciturn, and at the same time lose his appetite, seek repose, and display a suffering and dejected expression, we ought to examine him carefully: he is threatened with some acute disease. The development of symptoms will soon point out the seat and nature of the complaint, and consequently by what sorts of means it is to be opposed. But chronic affections are so slow in their approach and concealed in respect to their symptoms, that they often reach to a very advanced stage before their existence is suspected, unless the organs affected are examined before their diseased condition has manifested itself. We find the lungs full of tubercles, with cavernous excavations and abscesses, or in a state of atrophy, in the bodies of individuals who had neither coughed nor expectorated, nor experienced pain or dyspnoea during life; they had become gradually debilitated, had taken to their beds, and after a continually increasing emaciation, had at length sunk. The disorganization of the lungs had only been discovered by the aid of auscultation and percussion. We must not then wait for the expression of complaints on the part of lunatics in order to have our watchfulness excited to the means which are necessary for preserving their existence."

SECT. IV.—Of the causes of insanity.— *Predisposing causes.*

1. *Natural constitution.*—Among the circumstances in the previous condition of an individual which prepare him for sustaining the attack of this disease, the most important is a certain peculiarity of natural constitution. This consists chiefly, as it is probable, in a particular organization of the brain and nervous system, rendering those individuals so constituted liable to become insane when exposed to the influence of certain agencies, which in other persons either give rise to a different train of morbid phenomena, or are,

perhaps, devoid of any injurious effects. The constitutional peculiarity which predisposes to madness is not distinguished by any remarkable external characters. That such a natural tendency, however, actually exists, and in all instances is a necessary condition to the development of maniacal disease, is to be inferred from the consideration that similar exciting causes exert their influence on other persons without producing a like effect. Among the agents that give rise to madness, there is none more influential than intemperance, or the frequent use of ardent spirits. A considerable proportion of lunatics in the lower classes of society owe their disease to this cause. But it is only in a certain proportion of persons addicted to intemperance that the phenomena of madness make their appearance. Others, under the influence of the same noxious cause, are affected with apoplexy or paralysis; in many the brain escapes and the liver becomes disordered, or dropsy takes place, with or without disease of the liver; in some the lungs become the seat of morbid changes. It is evident that there must be an original difference in the habit of body whence arises the diversity of results brought about by the same or very similar external agencies. This original difference is apparently a peculiarity in the congenital constitution of each individual. It may be transmitted from parents, or it may arise *de novo*, as other varieties in the congenital structure are known to do. Hence it is comparatively of little moment, as far as an individual is concerned, to inquire whether his morbid predisposition has been derived by hereditary descent, or has sprung up with himself. It may, indeed, be observed that peculiarities which arise in a race are often common to several individuals even in the first generation. Albinos, for instance, though the offspring of parents of ordinary complexions, very frequently have brothers or sisters resembling themselves. In like manner, diseases which appear for the first time in a family often affect several members of it, who partake of the same peculiarity of temperament or congenital structure.

If these remarks are well founded, it must be apparent that hereditary madness is not less curable than a disease having symptoms of the same description, which has not been previously observed in the family of the person affected by it.

That the predisposition to madness, when it has once arisen, is frequently transmitted, is a fact too well established to admit of doubt; it constitutes a feature in the history of the disease.

The hereditary transmission of this tendency is remarked by M. Esquirol to be more general among the opulent than the lower classes. He states the proportion of hereditary cases among the former to be one-half, among the latter to be one-sixth. This, however, seems to be a mistake, as it appears by his table that of 351 cases at the Salpêtrière, 105, or nearly one-third, had the disease by inheritance. Among 264 patients of a superior class 150 cases were,

according to the same writer, hereditary. He accounts for this difference by referring to the exclusive marriages of aristocratical families, a cause which had formerly in France much influence. It remains to be determined whether the same difference is to be observed elsewhere under circumstances not admitting this explanation.

The same writer affirms that persons born before their parents had become maniacal are less subject to mental disease than those who are born after the malady had displayed itself. He makes a similar remark as to those who inherit the disease only on one side, in comparison with persons whose paternal and maternal ancestors had been affected by it. According to Burton the offspring of parents advanced in years are more subject than others to melancholy madness.

Another observation relating to the hereditary transmission of this morbid tendency is, that the disease is apt to shew itself in different individuals of a family at a particular period of life, and in all of them under a similar character. M. Esquirol has made this remark, and he has mentioned several facts in illustration of it. "Two sons of a merchant of Switzerland died insane at the age of nineteen years. A lady, aged twenty-five years, was attacked by puerperal madness; her daughter suffered in like manner at the same age. In one family the father, the son, and the grandson, all committed suicide about their fiftieth year. There was at the Salpêtrière a prostitute who had thrown herself into the river seven times; her sister drowned herself in a fit of intoxication. There exists near Nantes a family in which seven brothers and sisters are in a state of dementia. A gentleman, affected by the first events of the revolution, remained during ten years shut up in his chamber. His daughter, about the same age, fell into a similar state, and refused to quit her apartment. This predisposition, which manifests itself by external signs, by peculiarities in the moral and intellectual character of individuals, is not more surprising in connexion with madness than are the instances of gout, of phthisis pulmonalis, and other diseases, in a different point of view. It may be traced from the age of infancy: it furnishes the explanation of a multitude of caprices, irregularities, and anomalies, which at a very early period ought to put parents on their guard against the approach of insanity. It may furnish useful admonitions to those who preside over the education of children. It is advisable in such cases to give them an education tending to render the habit robust, and to harden it against the ordinary causes of madness, and particularly to place them under different circumstances from those with which their parents were environed. It is thus that we ought to put in practice the aphorism of Hippocrates, who advises to alter the constitution of individuals in order to prevent the diseases with which they are threatened by the hereditary predisposition of their family."

M. Esquirol affirms that many facts have,

occurred within the sphere of his information proving a strong predisposition to madness to have arisen from some accidental fright sustained by the mother during pregnancy. Marked cases of this description are said to have occurred during the period of the Revolution.

2. *Age*.—Persons in the middle period of life are most subject to attacks of insanity properly so termed. M. Esquirol has remarked that imbecility is the predominant mental disorder of childhood, mania of youth, melancholia of more advanced manhood, and dementia of old age.

The years during which madness most frequently makes its first appearance are those between thirty and forty in the age of the individual: next to these are the years between twenty and thirty; thirdly, are those between forty and fifty. Insanity is comparatively rare in the earlier as well as in the later periods. The case, however, of a child who had been maniacal from the age of two years was noted by Joseph Frank at St. Luke's in 1802. M. Esquirol mentions besides three instances of maniacal children. Dr. Haslam and others have reported some cases of the same description, but they are not of frequent occurrence.

M. Georget has observed that out of the number of 4409 lunatics in different hospitals in France and England, 356 were between the ages of ten and twenty, 106 from twenty to thirty, 1416 from thirty to forty, 861 from forty to fifty, 461 from fifty to sixty, 174 from sixty to seventy, and only 35 upwards of 70.

The following table, given by Dr. Burrows from Reports of the French hospitals, tends further to illustrate the proportional frequency of madness at different periods of life, and it has the advantage of distinguishing the sexes.

	Ages.	Men.	Women.	Total.
From 10 to 19	—	78	62	140
20 to 29	—	198	267	465
30 to 39	—	248	324	572
40 to 49	—	231	290	521
50 to 59	—	132	218	350
60 to 69	—	119	146	265
70 to 79	—	76	101	177
80 to 89	—	7	4	11
Ages unknown.	}	6	0	6
		1,095	1,412	2,507
Under 50 years of age.	}	755	943	1,698
Above 50 years of age.	}	340	469	809
				2,507

3. *Sex*.—If we may believe Cælius Aurelianus, madness was among the ancients more frequent in males than in females. In France, according to M. Esquirol, the reverse of this statement is true. This writer attributes the greater comparative liability of modern females to the vicious system of modern education, to the preference given to mere accomplishments,

to the reading of romances, which gives to young persons a precocious sensibility, premature desires, and ideas of perfection which they nowhere find realized, to the frequenting of plays and assemblies, the abuse of music, and want of occupation. In England, he observes, where women have an education more strengthening to the mind, and where they lead a more domestic life, the proportion of female lunatics to the male is less considerable. These considerations may account for the facts in respect to the higher orders, but as the observation includes those who are the inmates of hospitals, we must have recourse, in order to explain it, to the physical circumstances in which the condition of females differs from that of the male sex. The difference is in fact so great in France, that M. Pinel, in 1802, calculated that there were two female to one male lunatic. According to the report "Sur le service des aliénés," by M. Desportes, made at Paris in 1823, it appeared that from 1801 to 1821 the number of males admitted at the Bicêtre was 4552, and that of females at the Salpêtrière during the same period, 7223. At Bethlem, according to Dr. Haslam, 8874 lunatics were admitted in the course of forty-six years, of whom 4832 were females, and 4042 males. At St. Luke's, according to a statement made to a committee of the House of Commons in 1807, the number of females is usually greater than that of males by about one-third. In comparing a number of statements from different countries, M. Esquirol, however, concludes that the excess in the proportion of female lunatics is not so considerable as it is generally supposed to be, and that it does not, in fact, greatly exceed the difference which exists between the sexes in the ordinary state of the population. It is greater in some countries than in others, and in France than in England.

4. *Celibacy*.—M. Georget was inclined to reckon celibacy among the predisposing causes of madness, from considering the following facts detailed in the report of M. Desportes.

Out of 1726 female lunatics 980 were single women, 291 were widows, 397 were married persons.

Out of 764 males 492 were single, 59 were widowers, and 201 were married.

These relative numbers appear remarkable, but in estimating the result we must take into our account the fact that married persons lead in general more regular lives than the unmarried, that they are generally more fixed in their pursuits and their condition as to maintenance and employment, and less subject to causes which agitate the mind and excite strong emotions. These remarks apply, however, principally to men, and the difference is equally great among females.

5. *Temperament*.—A constitution of body predisposing to violent passions also predisposes to madness.

With respect to complexion, which is generally supposed to denote varieties of temperament, it does not appear that there is any particular shade or hue of eyes or hair which marks a predisposition to this disease. On a

comparison of facts collected from several countries, M. Esquirol has not been able to discover any decided difference. In the Parisian hospitals a chesnut colour of both eyes and hair prevails, which is the general colour among the people of the north of France.

6. *Season*.—M. Georget has given briefly the result of reports indicating the influence of seasons. It seems that during the six summer months a greater number of persons are received into the lunatic asylums than in the six months of winter.

7. Among the most powerful of the causes which render persons obnoxious to madness, must be reckoned previous attacks of the same disease. When such attacks have been repeated, the predisposition becomes increased. There are instances, however, of persons who during a certain period of their lives have been subject to repeated attacks of maniacal disease, but have recovered entirely, and have lived many years in a state of perfect sanity.

8. Other diseases of the brain, such as apoplexy and paralysis, sometimes predispose to madness, or are followed by it. Epilepsy of a severe and inveterate kind is sometimes complicated with insanity. These cases are distinct from the fatuity which is often the result of long-continued epilepsy. The form of maniacal disease connected with epilepsy is peculiar, and this may be considered as constituting a distinct disease. It has been ably described by the late Dr. Edward Percival.

9. *Education*.—An erroneous and unsuitable method of education is among the most influential causes of insanity. There are two different points of view under which the injurious effects of wrong education may be considered. By too great indulgence and a want of moral discipline, the passions acquire greater power, and a character is formed subject to caprice and to violent emotions; a predisposition to insanity is thus laid in the temper and moral affections of the individual. The exciting causes of madness have greater influence on persons of such habit than on those whose feelings are regulated. An overstrained and premature exercise of the intellectual powers is likewise a fault of education which predisposes to insanity, as it does also to other diseases of the brain. These are two considerations which are of the greatest importance with respect to the welfare of families to which an hereditary constitution may belong, rendering them more liable than others to cerebral diseases. They are distinct in themselves, and each might furnish a theme for an extensive treatise, most valuable in a practical point of view. Under the first head it would be necessary to consider the efficacy of those plans of education of which the professed object is to form a character remarkable for sedateness, for the strict discipline of the feelings, and, as far as this is attainable, for the abolition of strong passions and emotions. Such, undoubtedly, would be the kind of moral education best adapted for those who are constitutionally liable to insanity. The second remark, on the regulation of mental exercise in young persons whose

nervous systems are feebly constituted, has a more extensive bearing than on the subject of insanity. It brings forward a suggestion which is of general interest in these times in which mental exertion is stimulated to the utmost, and when in reality all the physical and moral powers are sacrificed to the cultivation of intellect, or in many instances to the mere acquisition of knowledge.

Exciting causes of madness.—The immediate causes of madness are in part physical agents, and in part moral. Perhaps it may be remarked that the former are the most prevalent causes of madness in the lower ranks of society, and the latter in the higher class, whose intellects are more developed, and whose minds are subjected to more extensive influences.

1. Among physical causes of madness, one of the most frequent is the immoderate use of intoxicating liquors. There is hardly a tribe of the human race who have not succeeded in inventing some method of producing intoxication. Ardent spirits are perhaps, of all, the most injurious in their effects, particularly on the lower classes in the northern countries of Europe and America. It has been repeatedly observed that a large proportion of the cases admitted into pauper lunatic asylums arise from this cause. They are in general to be reckoned among the cases most easily cured, for, although this is not uniformly the fact, it often happens that when the exciting cause is removed, the effect begins to lessen, and eventually ceases. When these patients are prevented from obtaining stimulating liquors, and are treated with sedative remedies, they quickly shew signs of amelioration and the subsidence of disease.

The use of opium and other stimulants is among the exciting causes of madness, though of much less general agency than the ordinary means of intoxication.

2. Blows on the head, and exposure to ardent solar heat, are well known to be occasionally the exciting causes of madness. It is plain that they act by bringing on inflammation, or a state bordering on inflammation, in the encephalon. The same remark may be made with respect to mercury, as used in syphilitic diseases. It is probably an error to suppose that syphilis is itself a cause of madness.

3. *Intestinal irritation*.—A disordered state of the intestinal canal often becomes a cause of disturbance in the brain, by whatever antecedents the former disease may have been induced. The state of the intestinal canal to which we allude is itself much more frequently of an inflammatory nature than it has generally been imagined, or at least than it was formerly supposed to be. In that condition of the canal which gives rise to costiveness alternating with diarrhoea, and accompanied with indigestion, flatulence and eructations, anorexia and nausea, transient but often acute pains in the hypochondria, livid and yellow suffusions of the skin, viscid secretions in the mouth, or redness of the fauces and palate with a glazed and dry surface, the whole train of symptoms often depends upon a low degree of chronic inflamma-

tion in the mucous membrane of the intestinal canal; and this is perhaps a frequent, if not an ordinary state in those cases in which disorders of the nervous system supervene on complaints of the stomach and bowels. This form of disease has been described by Dr. Ferriar and several other practical writers; but it is to M. Broussais that we are indebted for a more ample development of its pathology.

The enteric disorder, which lays the foundation for maniacal symptoms, as well as for other affections of the nervous system, is the result in different instances of various and very diverse noxious causes. The most frequent is excess in the use of stimulant and indigestible food. Too great indulgence of the appetite among the more opulent, and among the lower classes long-continued constipation, unwholesome diet, the use of salt provisions, exposure to cold and want, or neglect of warm clothing, give rise to diseases of the same description.

Intestinal worms are one of the results of constipation. Madness produced by the last mentioned cause is probably of very rare occurrence. M. Esquirol has, however, mentioned a remarkable instance of maniacal disease, affecting a young man, who was cured at two different periods by the expulsion of a large quantity of worms from the intestinal canal.

3. *Causes depending on states of the uterine system.*—States of the general system connected with irregularities of the uterine functions are well known to coexist with or to display themselves in various affections of the brain. Among them madness is one. Maniacal affections of this class may be mentioned under three heads.

a. *Dysmenorrhæal affections.*—Some females at the period of the catamenia undergo a considerable degree of nervous excitement: morbid dispositions of mind are displayed by them at these times, a wayward and capricious temper, excitability in the feelings, moroseness in disposition, a proneness to quarrel with their dearest relatives, and sometimes a dejection of mind approaching to melancholia. These are distinct from the cases of hysterical affection connected with the same periodical causes of excitement. The former are sometimes the preludes of a far more permanent disease.

b. *Suppressions of the catamenia.*—Sudden suppressions of the catamenia are frequently followed by diseases of the nervous system of various kinds. Females exposed to cold, undergoing powerful excitements, sustain a suppression of the catamenia, followed in some instances immediately by fits of epilepsy or hysteria, the attacks of which are so sudden as to illustrate the connexion of cause and effect. In attacks of madness the catamenia are for the most part wholly or partially suppressed during the early periods, and in many cases it is not easy to say whether the suppression is the effect or the cause of the disease. There are instances, however, in which the circumstances sufficiently indicate the order of connection. Dr. Burrows has detailed a case in which suppression brought on by mani-

fest causes was followed by mania. We have already alluded to the case of a young female mentioned by M. Esquirol, who suddenly exclaimed that she was cured of her disorder; her catamenia had flowed spontaneously, and her restoration to sanity was the immediate consequence. Facts so decisive in their bearings on pathology are not of very frequent occurrence, but their evidence reaches farther than the individual cases recorded.

It often happens that after some weeks or months in the duration of madness, the catamenia, though previously deficient, become restored nearly to their usual state. This, like the other indications of improvement in merely physical health, is only a favourable sign when it is accompanied by some amendment in the state of the mental faculties. Without any such change, it rather gives reason to apprehend that the disorder is becoming inveterate, and perhaps already making its transition from mania into an incipient stage of fatuity.

c. *Puerperal madness* is another modification of the disease connected with the state of the uterine functions. As this form of insanity is a most important subject, and in circumstances very peculiar, we shall allot a distinct section towards the conclusion of this treatise to the consideration of its history and pathology.

5. *Metastasis.*—The pathological fact, that diseases of the brain, and among others that from which madness results, supervene on the cessation of various discharges, on the healing of old ulcers, on the disappearance of cutaneous eruptions, on the cessation of inflammatory disease in membranous and other structures, on the removal of tumours, has been observed with greater or less attention by practical writers on medicine from the time of Hippocrates. Many cases illustrative of this fact are to be found in the works of Hildanus, Tulpius, and Hoffmann; and Sauvages, among the forms of madness, has reckoned one which he terms metastatic. M. Esquirol says that even a cessation of the usual discharge from the nostrils, of leucorrhœa, of blennorrhagia, as well as the disappearance of scabies, of herpes, of gout and rheumatism, has produced madness. In general it may be observed that the suppression of acute eruptions, whether pustular, exanthematic, or erysipelatous, is followed by acute inflammatory affections of the internal organs; in such cases the brain or its membranes are attacked by phrenitis or meningitis; while the disappearance of chronic disorder of the same class is the precursor of mental aberration. The suppression of more copious discharges, the removal of large tumours, the disappearance in dropsical cases by rapid absorption of deposited fluids without increased excretion, has been followed by determinations of blood to the head, giving rise to fatal apoplexy or severe convulsions.

6. *Moral causes of insanity.*—Among the moral causes of insanity we must reckon all the circumstances which are calculated to give rise to strong emotions, or to excite the passions. Strong emotions, by their operation on the nervous system, produce injurious effects on the

brain, and give rise to disturbed actions in that organ, whence arises mental derangement. The passions and emotions are indeed the principal and most frequently productive causes of madness.

In barbarous nations, among whom the mind is uncultivated, the passions are proportionally impetuous, but their sphere is limited, and the intellectual and moral faculties are very imperfectly developed. Madness is comparatively rare among such nations. According to Von Humboldt there are very few lunatics among the native Americans, and a similar observation has been made with respect to other uncivilized tribes. In Russia, Turkey, and China, madness is unfrequent. In the hospital of Grand Cairo, a city containing 300,000 people, M. Desgenettes found only fourteen lunatics. It must, however, not be forgotten that in such places many deranged persons are suffered to wander about through neglect and the absence of regulations for police, and that their numbers thus escape observation; yet this circumstance is not sufficient to account for the entire difference between barbarous and civilized countries, in respect to the apparent frequency and rarity of madness. It might be affirmed that mental derangement is the result of a deviation from the state of nature, if we were to agree with those who look upon barbarism as the natural condition of our species, and represent all that is ennobling and exalted, all that is good and really desirable in human life, as foreign or accidental, and the produce of forced and unnatural culture. In this as in other instances, it has pleased Providence to mix up with the greatest blessings some portions of evil, some ingredients of intense suffering: "*Medio de fonte leporum, Surgit amari aliquid, quod in ipsis floribus angat.*"

Various kinds of mental excitement have different degrees of influence in producing madness, under different social and political circumstances. Among the patients of the Salpêtrière, in 323 cases admitted during the years 1811, 1812, M. Esquirol reckoned 105 originating in domestic chagrins, 77 occasioned by poverty and reverses of fortune, 45 by disappointments in love, 38 by fright, 8 by fanaticism. Cases of what is termed religious madness are supposed to be much more frequent than this small proportion seems to imply, but it is much to be desired that we could determine the meaning of the expression religious madness, and to what examples of disease it may be correctly applied.

There can be no doubt that madness has often been produced by a vehement and impassioned style of preaching. "In the kingdom of Naples," says M. Berthollet, "a custom exists of preaching in favour of missions by a particular set of priests. In order to animate the faith of believers, they accompany their orations with particular acts, which are often of such a nature as to produce too powerful an effect on weak minds. They hold their hands over flaming torches, and whip themselves with scourges garnished with iron points. Their sermons are prolonged till the close of day, and

the feeble glare of a few flambeaus heightens the effect of the scene." "One of these sermons gave occasion to the case I am about to describe. The subject was *hell*: to heighten the colouring of the frightful picture which the preacher had traced, he took a skull in his hand, and having raised a question as to the abode of the soul to which it belonged, he exclaimed, invoking it, 'If thou art in heaven, intercede for us; if thou art in hell, utter curses.' He then cast it from him with violence. The lady, whose case is subsequently described in M. Berthollet's memoir, was instantly affected by a morbid change in the nervous system."

Strong emotions excited by vehement preaching produce continually in females and very sensitive persons, fits of hysteria, and in those who are predisposed to mania there can be no doubt that similar causes give rise to attacks of madness. Cases, indeed, are of continual occurrence which establish the fact.

But the terrors excited by a troubled conscience, which have given birth in the imagination to gorgons and chimeras, and monsters of darkness, are sufficient of themselves to produce madness in persons predisposed. None can entertain a doubt on this subject who recollect the stories of men persecuted by the Furies, the appalling self-tortures and mutilations, the blood-stained altars and the hideous divinities, the sacrifices of wives and daughters, the gloomy and hopeless fatalism of the pagan world. There is no remedy for these evils, resulting as they do from the moral and physical disorders of human nature, but the mild and consoling influence of Christianity; and if this religion has been made in some instances the instrument of evil rather than of good, we must recollect that the greatest blessings are capable of becoming by perversion the fertile sources of severe calamities. Perhaps some persons may suppose that if it were possible to divest the minds of men of all religious anxieties at once, together with all belief, they would be gainers by the change. But this experiment has been already tried in France, in a great part, during one period of the Revolution, and the following remarks of M. Esquirol display the results, as far as they relate to the increase or lessening of insanity.

"The changes," he observes, "which have taken place during the last thirty years in our moral sentiments and habits, have produced more instances of madness in France than all our political calamities. We have exchanged our ancient customs and fixed habits, our old and established sentiments and opinions, for speculative theories and dangerous innovations. Religion now only comes forward as a formal usage in the solemn transactions of life; it no longer affords its consolations to the afflicted, or hope to the desponding. Morality founded on religion is no longer the guide of reason in the narrow and difficult path of life. A cold egotism has dried up all the sources of sentiment; there no longer exist domestic affections, respect, attachment, authority, or reciprocal dependences; every one lives for himself; none are anxious to form those wise and salu-

tary provisions which ought to connect the present age with those which are destined to follow it."

SECT. v. — *Necroscopical investigations of madness.*

Recourse has been had to anatomical investigations with a view to illustrate the pathology of madness, and although such researches have not answered fully the expectations with which they were entered upon, they have led to results by no means devoid of interest in their physiological bearing, and capable, though to a limited extent only, of practical application.

This department, as well as most others, of pathological anatomy, may be said to begin with Morgagni. That celebrated writer has, however, related the details of but seven or eight dissections referring to cases of insanity. In these he remarked several facts which later observations have confirmed. He found the substance of the cerebral hemispheres more firm, and that of the cerebellum softer than natural. In one instance the white substance of the cerebrum was hard and of a brownish hue, and its bloodvessels, as well as those of the plexus choroides, much distended with blood: in another there was hardening of the hemispheres and softening of the fornix, fullness of the cerebral vessels, adhesion of the pia mater: in a third, injection of the meninges and the plexus, hardening of the brain, and softening of the cerebellum. This writer mentions also collections of serous fluid in the ventricles and in the tissue of the pia mater.

The researches of Greding were much more extensive, and his observations more various. Among the facts remarked by him are thickenings of the cranium, either partially or generally observed in 167 ordinary maniacal cases out of 216, in 78 out of 100 cases of raving madness, and in 22 out of 30 cases of idiotism or imbecility; softness of the brain in 51 cases out of 100, especially in mania complicated with epilepsy; wasting of the optic thalami in two cases of dementia; enlargement and contraction of the ventricles; serosity in these cavities, or dryness of their surfaces; adherence of the dura mater to the skull; thickened and blue colour of the pia mater; softness of the tubercula quadrigemina; osseous or stony concretions in the cerebellum.

Dr. Haslam has given the details of 37 cases of madness with the appearances discovered on dissection. In not one of these cases were the brain and its membranes free from morbid appearances. In almost all, the membranes either bore marks of former inflammation or were distended with blood: in 16 cases there was an effusion of serum between the membranes, and in the lateral ventricles this was observed eighteen times. In nine cases the consistence of the brain was firmer than usual; in seven it was softer, but in 20 not perceptibly altered. In three cases the cranium was thicker, and in three thinner than the natural state. In several cases a peculiar looseness of the scalp was observed.

The following are the most remarkable of

the observations made by M. Esquirol on the morbid appearances of the brain in madness. The cranium thick and compact; in other cases thin and porous; often injected with blood: crania irregular in respect to the different diameters, and to the cavity of the two sides. Membranes thickened in 11, injected in 19 cases. Basilar arteries ossified in five cases. Cerebrum dense in 15, soft in 19 cases. Cerebellum dense in 12, soft in 17 cases. Grey substance abundant in five, discoloured in 15 cases. White substance injected in 19 cases. Adhesions of the lining membrane of the ventricles in 54 cases. Serous depositions frequent between the pia mater and the arachnoid, as well as in the ventricles. Plexus choroides displaying almost always serous vesicles, (kystes séreuses.) Many other morbid changes have been pointed out by the same writer, such as tumours, vesicles (kystes), partial softenings and ossifications of the arachnoid. Two cases of acute maniacal disease, observed by M. Esquirol, are recorded by M. Georget,* in which the brain presented all the characteristics of intense inflammation.

M. Georget has recorded with great precision the facts which he has himself observed. The following are the most remarkable. Irregular conformations of the cranium, the prominences of which are developed irregularly, those of the right side being generally larger than those of the left; some skulls having the lateral diameter of equal extent with the antero-posterior, and the cavities of the base irregular in extent; some skulls, one in 20, thickened partially or generally; more frequently the bones hard, white, without diploe, resembling ivory; some very light. Dura mater rarely changed; sometimes adherent to the skull, thickened, containing deposits of bone. Arachnoid displaying in places additional laminae of a red or grey colour; sometimes thickened but smooth. Pia mater injected; or thickened and infiltrated with serum, giving at first the appearance of a gelatinous deposit. Volume of the brain sometimes less than the cavity of the cranium seems to require. Some brains very hard, cut with difficulty; the white substance glutinous, elastic, and suffering distention; more frequently the brain is soft, the grey matter being pale and yellowish, and the white substance discoloured, of a dirty white, the colour and consistence of these portions almost confounded. The convolutions separated by serosity and the pia mater thickened. Interior cavities of the brain appearing in some instances very large, in others small, often filled with a serous fluid remarkably clear and limpid; plexus choroides exanguineous, containing hydatiform vesicles. Partial softenings of the brain; erosions, ulcerations of the surface of the ventricles. Cerebellum generally softer than the cerebrum; sometimes partially softened. Mesocephalon, medulla oblongata, and medulla spinalis rarely display morbid changes of structure.

M. Georget has thus summed up in a short compass the morbid changes which have been

* Art. *Encéphalite*, in the *Dict. de Médecine*.

observed in the heads of maniacal subjects.

1. Bones of the cranium sometimes thickened, sometimes without diploë, thick and resembling ivory; sometimes light and spongy; inequalities in the form of the cranial cavity.

2. Injections, thickenings, serous infiltrations, of the pia mater; separations and attenuations of the cerebral convolutions. 3. Surface of the cerebrum softened and adhering to the pia mater, so that the latter, when pulled off, raises portions of the cerebral substance with it; injected state of the cerebral substance, reddened colour of the grey portion, marbled violet hues in the white portion, increased consistence of both; discoloration and general softening of the cerebrum, grey substance yellowish, white substance of a dirty white; serous collections in the ventricles, particularly in the lateral ventricles; partial softenings. Other alterations are much less frequent; the annular protuberance, and the four great nervous trunks which take their rise from it, the medulla oblongata and the medulla spinalis, are rarely found to have undergone any material change of structure.

Some curious and interesting additions have been made to the morbid anatomy of madness by M. Foville, whose researches were conducted with great accuracy. It was a part of his plan to compare, in every instance on the spot, healthy brains with those which were the subjects of examination as having appertained to maniacal patients. By this method some minute peculiarities of structure seem to have been detected which might otherwise have escaped notice. M. Foville's inquiries were carried on at the Salpêtrière in conjunction with his colleagues, MM. Delaye and Pinel Grandchamp, when that hospital was under the superintendence of M. Esquirol, and subsequently by himself at the establishment of the Lower Seine, an extensive receptacle for lunatics, which has been for some years under his immediate care. His observations are arranged under the following heads: 1. morbid changes in the cortical substance; 2. changes in the white or fibrous substance; 3. changes in the nerves of sensation; 4. changes in the membranes; 5. observations on the skull and the hairy scalp; 6. changes observed in idiots. We shall abstract the most remarkable phenomena noticed under several of these divisions.

1. *Changes in the grey substance.*—In the most acute cases the surface of the cortical portion presents, on the removal of the membranes, a most intense redness, approaching to that of erysipelas. This is still more marked in the substance of the grey matter itself; it is more striking in the frontal region than on the temporal lobes, and in the higher regions than in the posterior parts of the brain. In brief terms the morbid changes observed by M. Foville in acute cases of madness are nearly confined to the following: "Red colour, uniform and very intense; numerous mottled spots, varying from a bright to a violet red, bloody points, minute extravasations of blood; diminished consistence in the thickness of the cortical substance, coincident mostly with a slight increase of consistence in its surface; dilatation of the

vessels, resistance of their parietes." In acute cases M. Foville has never observed adhesions of the membranes to the cortical substance. Such adhesions are very frequent in chronic cases, and hence, as he conjectures, may be explained the curable nature of recent maniacal affections, and the hopeless and incurable state of those patients who have long laboured under madness or dementia.

Among the chronic changes of the cortical substance, the most frequent is a very perceptible increase of firmness and density in the superficial part, extending to no great depth, but uniform, constituting a distinct lamina, smooth externally, but internally irregular, of lighter colour than usual, which, when torn off, leaves the remainder of the cortical substance red, soft, and mammillated, somewhat resembling granulations. Something like this external pseudo-membrane of the cortical substance has been noticed in wild animals which have died in a state of confinement, by M. Foville, and is conjectured by him to denote a cerebral disease in them. The pale and almost bleached hue of the surface of the cortical portion is always connected with this increased density in its substance. Sometimes the surface is rough and granulated, containing small grains of a yellowish white.

In conjunction with these changes the volume of the convolutions remains natural, or is less than usual. When lessened, there are sometimes linear depressions or irregular pittings on the surface of the convolutions, and in the cortical substance itself there are small yellowish lacunæ filled with a serosity of the same tinge. These lacunæ are supposed to correspond with the minute extravasations observed in acute cases. In other instances the diminution of volume is a real atrophy of the convolutions, which appear thin and angular, as if pinched up towards their extremities. This morbid change corresponds with what MM. Gall and Desmoulins have termed atrophy of the convolutions. It is very frequent in the frontal regions of the hemispheres. It often comprises particularly three or four convolutions on each side of the sagittal suture, a chasm filled with serosity occupying the place left by absorption of the cerebral substance. Co-extensive with this appearance is that species of atrophy in the cranium in which the diploë disappears, and the external lamina approaches the internal, leaving a superficial depression on the head. In these cases of atrophy of the convolutions, the diminution of substance is confined frequently to the cortical or grey matter. What remains of the cortical substance is harder than natural, and sometimes presents, when carefully examined, a really fibrous structure; it is of darker colour, or seems to separate into layers, of which the exterior is pale and the interior of a rose colour.

Another state of the cortical substance observed in chronic cases of madness is that of softening (*ramollissement*); this is entirely distinct from the softened state of the external portion already described. The whole thickness of the grey substance is equally altered in

these cases; its colour is more brown than usual; its consistence almost liquefied.

This extreme and general softness of the cortical substance does not necessarily accompany a similar state in the white substance; it is sometimes conjoined with a hardened state of the medullary portion. In such instances the grey may be separated from the white matter by pouring water upon it. Appearances of this kind seem to belong to cases of the last degree of dementia, with general paralysis and marasmus. M. Foville mentions cases apparently of the same nature, in which limited portions of the grey substance had disappeared previously to death. M. Calmeil, in his work on the paralysis connected with insanity, has related two instances of a similar description.

It seems that the grey substance in other parts of the brain is not subject to a similar change; its morbid alterations coincide with those of the medullary portion. From this remark must be excepted the cortical substance of the cornu ammonis, which is sometimes softened, and at others of a scirrhous hardness.

2. *Morbid changes of the white substance.*—Morbid alterations of the white or fibrous substance in mad persons are in relation to its colour, its density, and its texture.

The white substance is often the seat of vascular injections; sometimes vessels of a certain size being affected, the appearance of bloody points is produced on the section of the white substance. In other instances a finer injection gives rise to a mottled appearance of a deep red or violet colour. A magnifying glass is required in order to discover the vascular injection which produces this appearance. These injections of the white fibrous substance do not always coincide with similar injections of the surrounding cortical substance.

It is not rare to find in lunatics the fibrous substance of a splendid white; this particular aspect generally corresponds with an increased density of the parts. The hardness of such parts of the brain is sometimes almost fibro-cartilaginous. The induration of the medullary substance is, however, not always connected with this remarkable whiteness; sometimes the hardened medullary substance has a yellow tinge or a grey leaden colour. M. Foville attempts to account for this hardening of the fibrous portion of the brain by the supposition that each cerebral fibre has contracted morbid adhesions with the surrounding fibres, so as to render their separation impossible. This opinion is offered as more than conjecture with respect to the different planes of medullary substance, of which it is considered as proved that the white substance of the brain consists. The fibrous mass of the hemispheres results, according to this writer, from the super-position of several distinct layers or planes, applied one upon the other, and connected by means of a very fine cellular tissue. These planes are easily separable in the healthy state, but in the state of maniacal induration they are inseparable.

Among lunatics affected with general para-

lysis, M. Foville has found these adhesions wanting in only two cases; and in these two instances the cerebral nerves, the annular protuberance, and the medulla oblongata presented an extreme hardness. The same alteration has been found in the brains of old men whose voluntary movements have become uncertain or vacillating; it has never been seen in lunatics whose muscular powers had remained unimpaired.

The brains of some lunatics are so full of serous fluids, that an abundant serosity flows from the surface of incisions; sometimes this serous infiltration is so abundant as to deserve the name of cerebral œdema. A change more rare, which M. Esquirol has remarked, was the presence in the brain of a multitude of small cavities, from the size of a millet-seed to that of a nut, containing a limpid fluid. The section of a brain thus changed is compared to that of a porous cheese. The cavities are supposed to be the sequelæ of extravasations.

The changes in the structure of the cerebellum are analogous in kind to those of the cerebrum, but much more rare.

Tubercles and other tumours in the brain are not considered by M. Foville among the causes of madness properly so termed.

3. *Morbid changes in the nerves.*—M. Foville is persuaded that he has traced morbid alterations in the nerves corresponding with peculiar phenomena of sensation. In a female lunatic, tormented by hallucinations of sight, the optic nerves were found hard and semi-transparent through a great part of their thickness.

4. *Morbid changes in the membranes.*—In acute cases, the only morbid appearance discovered in the meninges is for the most part injection of the pia mater. This injection is generally proportioned to the degree of inflammation in the cortical substance of the convolutions. The small arteries and veins, passing from the membrane and penetrating the grey matter, are seen distended with florid or black blood: the arachnoid in the mean time preserves its natural aspect.

The chronic changes in the membranes consist for the most part in opacity, increased consistence, thickness of the arachnoid, the formation of granulations, and pseudo-membranes on its surface, and the effusion of serosity into the cellular tissue of the pia mater and the ventricles.

The arachnoid membrane displays either extensively or in patches a pearly whiteness. The opacity never exists without thickening; and in those places where the arachnoid and pia mater are naturally contiguous, they are found to be adherent. These opaque patches, as M. Foville supposes, result from the deposition of albuminous layers upon the arachnoid.

The observations of the same writer on the peculiarities observed in the skulls of lunatics add little to our previous knowledge on this subject; and his remarks on the conformation and texture of the brain in cases of idiotism do not necessarily belong to the subject with

which we are now engaged. We shall conclude our abstract of his observations by briefly citing his general inferences.

"The morbid changes which we have surveyed present many of the anatomical characters of inflammation; intense, general, diffused redness; in many cases tumefaction; and lastly, in passing to the chronic state, the formation of adhesions between the cortical substance of the convolutions and the contiguous membrane; besides this, adhesion of the different planes or layers of the cerebral substance to each other in a certain number of cases.

"If the simple redness, the perceptible tumefaction—if the general and partial softenings, the increased resistance which we have noted in acute cases, left any doubt of the true nature of the organic disorder, the adhesions observed so often in chronic cases certainly admit of none; and we are forced to allow that there exists in the brains of lunatics a state of true inflammation, unless we cease to regard the adhesions observed in other parts as undoubted traces of such a state, and refuse to admit that adhesions of the pleura, peritoneum, and pericardium, afford evidence of the former existence of pleuritis, peritonitis, and pericarditis.

"As the different traces of inflammation are more constant in the brain than in the membranes, it is necessary to conclude that the essential change has taken place in the brain, and that the change produced in the membranes is only accidentally complicated with it." In his remarks on this subject M. Foville plainly means to express his dissent from the opinions maintained by M. Bayle, who, in his treatise "*Des Maladies du Cerveau*," attributes insanity to disease of the membranes.

Among the morbid appearances of the brain, the varied changes of the cortical substance are the most constant in connection with symptoms of mental derangement. Although M. Calmeil maintained a different opinion, and was inclined to ascribe paralysis or the loss of muscular power to disease of the cortical substance, the facts on which he founded this inference do not, as M. Foville contends, warrant such a conclusion. In all instances of the general paralysis of lunatics which he has examined by dissection, there was, besides the change in the cortical substance, some alteration, either hardening, serous infiltration, or softening of the white substance; and in most cases, in addition to these appearances, there were adhesions of the principal planes of the cerebral substance to each other. A very remarkable case which occurred in the clinical course of M. Esquirol in 1823, affords strong evidence in favour of M. Foville's argument. The cerebrum of an idiot displayed the grey substance of both hemispheres in the last stage of atrophy and disorganization, while the white portion of the brain remained perfect on one side. In this person the intellect had been entirely defective, but the muscular power on one side only had failed. From this and similar observations M. Foville concludes that the function of the enervous portion of the brain is essentially connected with the intellectual operations, and

that of the fibrous or white structure with muscular action. His two principal inferences are expressed in the following terms:

1st. Morbid changes in the cortical substance are directly connected with intellectual derangement.

2d. Morbid changes in the white substance are directly connected with disorders in the motive powers.

The remarkable accuracy of these researches throws a strong shade of doubt, and even of improbability, over those recorded cases of maniacal disease in which *no morbid traces* were discovered in the anatomical examination. There is much reason for suspecting that a more exact scrutiny, and a careful comparison of the state of the parts with the appearances displayed by the same organ in a natural and healthy condition, might have led, in some of these instances, to the detection of morbid lesions greater or less in extent. Yet it is not improbable that degrees and modifications of maniacal disorder have taken place, in which such changes might have been, in an early stage, hardly to be traced *with certainty*. In cases of insanity displaying no general disturbance of the intellectual operations, and principally consisting in a morbid state of the temper and affections, and in recent examples of monomania, we should not expect to find strongly marked changes in the brain, and there is indeed but little proof that the brain is in some of these cases diseased. And where there is more considerable disorder in the functions of the brain, arising secondarily or by sympathy with the state of other organs, the traces of such disorder may be very evanescent. It has likewise been remarked by M. Foville, that in some accidental affections of the maniacal class, succeeding the action of debilitating causes, as in the puerperal state, nothing has been discovered in the brain more striking than its extreme and general paleness, and that, although there are in these instances some mottled appearances of a light red or rose colour on the cortical substance, such changes are too slight to be considered as idiopathic. The same writer adds that in the small number of cases of this description which he has had an opportunity of examining, the disorder in the brain has appeared to him to be sympathetic of some deeply-seated disease of the uterus or abdomen. In general, however, the fact is unquestionable that insanity depends upon organic lesion of the brain, and we have sufficient reason to conclude that this lesion is, in its commencement, a degree or modification of inflammatory action.

SECT. VI.—*Treatment of madness.*

Division of the subject. Moral and medical treatment.—The proximate or immediate cause of mental derangement is so much concealed from our research, the phenomena of the disease are so complicated, and the morbid states of the constitution with which they are connected so various, that we might foresee no ordinary difficulty in the attempt to lay down, with respect to this class of disorders, any gene-

ral principles or indications of cure. In reality this task has been found to be a more arduous one than even the circumstances adverted to would have led us to anticipate; and hence many writers have given it up, and rest satisfied with stating as merely experimental results the effects which particular remedies have been thought to produce.

It is usual to divide under two heads the different means which suggest themselves to our consideration for the cure of madness, and to take up separately what relates to the moral treatment of the insane, or the means supposed likely to exercise a beneficial influence on the mind; and, secondly, the medical or therapeutical remedies, properly so termed. As this mode of arrangement is attended with some advantages, and as no practical objection has been raised against it, we shall keep it in mind in proceeding to the subjects now to be considered, beginning with the medical or therapeutical treatment of insanity.

Medical treatment of insanity.—The medical treatment of insanity may be referred in a great measure to two indications or principles, which in many cases may be followed more or less fully, and will in general serve the purpose of associating in the mind the different curative attempts which may be made with some hope of success. There are, indeed, instances of the disease to which these indications are either inadmissible, or can only be adopted in a very limited extent; but such cases may be considered as exceptions.

I. The first indication is to remove or lessen that diseased condition of the brain on which we have reason to believe that madness is, in some part at least, dependent.

That the diseased condition of the brain here referred to is nearly allied to inflammation, that all its essential pathological characters are those of inflammation, may be concluded from the following considerations.

1. The morbid appearances displayed by anatomical researches in the brain and its investments are, as we have seen, generally referable to the immediate results or more remote vestiges of inflammatory action. On this head we shall add nothing to what has already been said in the last section, and refer the reader particularly to the facts there accumulated, and the concluding remarks upon them.

2. The relations of madness to other diseases, which are known to be connected with increased vascular action, or at least with increased fulness in the vessels of the brain, tend to support the same inference. The connection of apoplexy and paralysis, of epilepsy and of other cerebral diseases, with madness, has been pointed out by medical writers. These diseases are occasionally converted into each other, or mutually succeed each other, and undergo alternations. They display such a relation as leads us to believe that the proximate causes or the morbid changes on which the symptoms immediately depend, are in all analogous. Therefore, as some of the class, apoplexy for instance, and paralysis, are connected with vascular fulness in the brain, it is hence probable that a

state not far removed from this, and at least likely, under the influence of slight causes, to pass into it, gives rise to the phenomena of madness.

The metastasis of inflammatory diseases from other parts of the body, among which is included the recession of cutaneous eruptions, is well known to be followed not unfrequently by the appearance of maniacal symptoms. Suppressions of catamenia and other discharges, giving rise to similar diseases, strongly confirm the same pathological principles.

3. The causes in general which excite madness bring us to the same conclusion. These are principally of a description likely to give rise either to inflammation in the brain, or to a full and distended state in the vessels of that organ. Exposure to severe heat or cold, insolation, concussion or other injuries of the head, intoxication, and generally excess in the use of stimuli, great mental excitement, are all of this class; the condition of the brain, which it is the tendency of these agents to promote, is either inflammation, or something bordering upon it.

These different considerations concur in rendering it probable that the actual condition of the brain which immediately gives rise to the phenomena of madness, is in general one of high vascular excitement or turgescence, a state which, if it does not really constitute inflammation, is at least closely bordering upon it, and so liable to pass into it, that all the usual consequences of inflammation in many instances arise from it.

But though we may be correct in drawing this inference as a general one, there are great difficulties to be overcome, and much remains to be proved, before we can be authorized to insist upon it as universally applicable. The phenomena of mental disease are so various, and even so diverse, that they may be thought, not improbably, to arise from very different states of the system. There are instances of mental disease conjoined with so much atony and debility, subsidence of vascular action, coldness of surface, and diminished secretions, as to indicate a very different state from that of inflammation. Anatomical researches display in these instances a pale discoloration of the brain, with abundance of serous fluid, softenings of substance, and other phenomena of a similar description. Here we trace a state different from inflammation, though perhaps its remote consequence.

Are there not, likewise, cases in which we are scarcely authorized to conclude that any disease of the brain has ever existed? Instances of moral insanity, in which obliquity of character exists through life, and scarcely ever amounts to aberration of intellect, and some cases of monomania, in which slight and transient hallucinations supervene upon moral obliquities of the same description, and appear at intervals, cannot perhaps be referred with any degree of probability to an active state of disease in the encephalon.

It is probable, on the whole, that such exceptions bear a small proportion to the number

of cases to which the preceding remarks on the pathology of madness are applicable.

If these remarks are well founded, they lead at least to one practical indication for the general treatment of madness. In proceeding with the medical treatment of maniacal diseases, we shall do well to bear constantly in mind the probable condition of the brain, and to direct our practice more or less with a reference to it.

Yet we must not omit to observe that the physician who proceeds to treat cases of madness as instances simply of inflammation in the brain, and who expects to cure it at once, like any other local inflammatory disease, by the direct operation of antiphlogistic means, will very often find himself greatly disappointed. He will meet with many cases in which no perceptible benefit arises from bleedings, evacuations of all kinds whether general or locally applied, and combined with the whole series of remedies supposed to be required by the existence of organic inflammation. Many patients will sink under such a course of treatment if carried on incautiously: it will leave the disease undiminished, and exhaust the powers of life. This depends, perhaps, on the influence of diseased states in other structures and organs, or on disordered functions of other parts which are complicated with, and in some instances give rise to, the disturbance existing in the brain. Inflammatory excitement is a part of the disease, but does not entirely constitute it, even in so far as the brain is concerned.

Perhaps we may venture on the assertion, that there are few instances of madness in which the practical indication arising from the view which we have taken of the pathology of this disease will not be found applicable during some periods of the case, though in many its application is very limited. The degrees in which it is admissible are very various.

In recent cases of mania, properly so termed, and of incoherent insanity, particularly in young and plethoric subjects, and where the disease has made its attack suddenly, and is accompanied with signs of considerable vascular excitement, much may be hoped from the antiphlogistic treatment, at least from certain parts of it judiciously modified. We shall now consider the different means of which it consists, and advert to the opinions of some of the most eminent practical writers with respect to their use in cases of insanity.

1. *Of bleeding.*—Cullen recommends bleeding in the early stage of madness. He says that it has been common to employ this remedy in all cases of recent mania, and, as he thinks, with advantage. He observes that when the disease has subsisted for some time, he has seldom found bloodletting to be of service. "It is," he says, "a proper and even a necessary remedy in those instances of madness in which there is fulness and frequency of pulse, and when marks are observed of increased impetus in the vessels of the head." He prefers bleeding from the arm, while the patient remains in somewhat of an erect posture,

and bringing on a degree of deliquium, which, he says, is a pretty certain mark of diminished fulness and tension in the vessels of the encephalon.

Pinel, whose authority could not fail to produce an impression, is in this respect decidedly opposed to Cullen. He considers the signs of vascular plethora in the head, or of determination of the blood thither, as very deceptive; and although he allows bleeding to be in some instances capable of averting attacks of recurrent madness when they are anticipated, he carefully abstains from the use of the lancet after the disease has actually broken out. Care is always taken, he says, to question the relatives of patients admitted into the hospital over which he presided, whether bleeding has been practised, and if so, what were its results. "The reply always proves that the state of the patient has changed for the worse immediately after bleeding." Pinel held very firmly the opinion that bleeding, even in maniacal cases which are accompanied by circumstances supposed to indicate plethora and local determination to the head, tends to retard recovery, to render it more doubtful. He is even persuaded that bleeding gives to the disease a tendency to degenerate into dementia or idiotism. The facts, however, which this distinguished author adduces as proofs of his opinion, afford, as M. Foville has remarked, but very equivocal evidence. "Two girls," he says, "nearly of the same age and temperament, were admitted into the hospital (the Salpêtrière) on the same day: one of them, who had not been bled, was cured in the space of two months; the other had undergone a copious bleeding. She sank into a state of idiotism, or rather of dementia, and did not recover the faculty of speech till the fifth month. Her perfect restoration took place at the end of the ninth month." Now, as most authors fix the mean duration of madness at the period of several months, and some at more than a year, this case of recovery at the end of the ninth month cannot afford a strong condemnation of the practice pursued. Another case, which the same author has adduced as affording evidence against bleeding, is not more conclusive in respect to the influence of remedies on the ultimate event of the disease. Yet the opinion of such a writer, founded as it was, at least by himself supposed to have been, on extensive observation, ought not to be entirely disregarded because he happened to select but dubious illustrations. If bleeding occasions a state of collapse in the system, and is carried beyond what is necessary to reduce an over-excitement, a fatuous dejection of mind is likely, in some cases, to be the result.

M. Esquirol coincides with Pinel in the opinion that the diseased state on which mental derangement depends, is sometimes changed for the worse by bleeding. He says that he has seen madness increased after an abundant flow of the catamenia, and likewise after one, two, or three bloodlettings. In such cases melancholy dejection has passed into furious madness. Yet M. Esquirol approves of mo-

derate bleeding in plethoric cases, and where some habitual sanguineous evacuation has been suppressed. He has often with advantage applied leeches behind the head or to the temples of patients who are subject to sudden determinations of blood towards the head. His favorite remedies in such cases were the use of a few leeches at a time, repeated as often as necessary, and cold applications to the head.

To outweigh the authority of those writers who either condemn the practice of bleeding in madness, or allow of its adoption in so sparing a degree, strong evidence is requisite, but such evidence we possess.

Dr. Haslam says that bleeding is the most beneficial remedy that has been employed in madness, and that it is equally beneficial in melancholic as in maniacal cases. He limits its use to recent cases and plethoric habits, and directs it to be performed by the application of six or eight cupping-glasses to the shaven scalp. The quantity of blood to be taken must depend on circumstances. "From eight to sixteen ounces may be drawn, and the operation repeated as circumstances may require." When a stupid state has succeeded to one of high excitement, Dr. Haslam considers bleeding as contra-indicated.

But Dr. Rush is the most strenuous advocate for bleeding in maniacal cases. He lays the greatest stress on this remedy, and has perhaps carried its use to a greater extent than any other medical practitioner of high repute. The arguments which he has given in support of the practice of large depletion in madness are the following:—1. The force and frequency of the pulse, the sleepless and agitated state of maniacal patients. 2. The appetite being unimpaired in lunatics, and sometimes even stronger than usual, a plethoric state of the vessels easily arises in such habits. 3. The importance of the diseased organ, the delicate structure of the brain, which prevents it from long supporting morbid action without being exposed to the danger of permanent disorganization. This danger, he says, is much increased by the want of sleep, the cries and exclamations, and the constant agitation of mad persons. 4. The want of any natural channel of discharge from the brain, by which the ordinary results of inflammation might be averted or got rid of, in that way by which serous discharges in other parts relieve the inflammatory state. 5. The accidental cures which have followed the loss of a large quantity of blood. Dr. Rush has seen several lunatics who had attempted self-destruction by cutting their throats, or opening the great vessels, cured by the abundant hemorrhages which have followed these attempts. 6. Lastly, he says that bleeding is indicated by the extraordinary success which has resulted from its use in the United States, and particularly at the hospital for lunatics in Pennsylvania.

Dr. Rush advises large bleedings at the first attack of mania. If the patient bears it without syncope, he ought to lose, according to this physician, from twenty to forty ounces of

blood. If possible, it should be taken from him while standing erect. Free bloodlettings practised early in the disease have, as he says, a surprising effect in calming the patient, and in many instances are sufficient for the cure unaided by any other remedies. In most cases, however, bleeding from the arm is to be followed by the application of leeches or cupping-glasses to the head or nape of the neck, by low diet, antiphlogistic remedies, refrigerants applied to the head, and the use of warm or tepid baths.

Dr. Rush was of opinion that the evacuation of blood ought to be carried to a greater extent in madness than in any other acute disease whatever. From a patient, sixty-eight years of age, he caused two hundred ounces of blood to be drawn in less than two months. Another patient of Dr. Rush lost four hundred and seventy ounces by forty-seven bleedings in the course of seven months.

We shall conclude this survey of the conflicting opinions of practical writers on the expediency of bleeding in madness, by the following observations of M. Foville, which are deserving of the most attentive consideration, and which in our opinion place the subject in the true point of view. He says, "Without ever having pushed the employment of this remedy so far as Rush and Joseph Frank, I confess that it appears to me to be one of those on the efficacy of which the greatest reliance may be placed. MM. Pinel and Esquirol have proved that the 'expectant method,' assisted by a few simple rules, and a moral treatment wisely directed, have succeeded in a great many cases; but although it is better to confine ourselves to the use of simple means, patiently continued, than to employ unadvisedly the method of interference, I believe that the physician devoted to the study of pathological anatomy can draw from the results which it furnishes, compared with the observation of symptoms, valuable therapeutic inductions; that he may place reliance on their efficacy, and recommend them with confidence when experience shall have demonstrated their good effects. Are not the anatomical characters which so constantly present themselves in acute cases, and the adhesions which are so frequent in chronic ones, evident proofs of inflammation? And hence, are we not authorized to hope for advantages from the use of antiphlogistic means?"

"If it be added," says M. Foville, "that in several hundred lunatics, whose bodies my situation for nearly ten years has given me an opportunity of examining, I have never found adhesions in acute cases, while they have been very common in chronic cases; if, with these facts, the results related in the works of MM. Bayle and Calmeil are compared, we may conclude, on seeing these adhesions so frequent in chronic cases, that they are incompatible with the regular exercise of an organ so delicate as the brain, and consequently incompatible with the return of reason. Hence we ought, in every acute case, to choose the most active means, in order to prevent this

melancholy termination of the cerebral disease.

"Such are some of the reasons which have led me to agree with several physicians who have been placed in circumstances favourable for making observations, that bleedings ought not to be entirely proscribed in the treatment of mental diseases. In the greatest number of cases of recent insanity which have been placed under my care, I have employed evacuations of blood, local or general, rare or frequent, abundant or in moderation, according to the strength of the patient, and the state of the pulse, the redness of the eyes, the heat of the head, the agitation and want of sleep. I have always preferred general bleeding, when there existed a state of plethora, which the force and frequency of the pulse evinced. In opposite circumstances, leeches on the neck, the temples, behind the ears, cupping upon the same part, and upon the shaved head, have produced decided benefit. Local bleeding having appeared to me to produce a marked effect upon the brain, I have often prescribed it at the same time with a general bleeding in the case where the intensity of the general phenomena has imperiously demanded the latter; but I have never rested exclusively upon the efficacy of sanguineous evacuations, although in many cases I have seen all the morbid symptoms disappear, as if by enchantment, under their use.

"I have under my care several patients subject for a number of years to attacks of intermittent madness, which, left to nature, would last three or four months, or longer.

"During three years, that is, since they have been confided to my care, they have not experienced a single attack of a month's duration. Often in the space of five or six days all the symptoms have been dissipated. General or local bleedings proportioned to the intensity of the symptoms, warm baths with cold applications to the head at the same time, are the means by which I have constantly averted the attack.

"I have several times prevented the return of these attacks by employing the same treatment, as soon as the redness of the eyes, the heat of the head, and wakefulness manifested themselves, even when there had been no delirium."

The writer of the present article having superintended during nearly twenty years a receptacle for maniacal paupers, has possessed adequate opportunity of forming an opinion on the ground of his own experience as to the efficacy of different remedies, and among other practical questions with reference to the treatment of insanity, as to the extent to which bloodletting is advisable in this disease. The results of his own observation lead him to doubt the propriety of the copious blood-lettings of which Dr. Rush is the advocate. He believes the cases of madness to be comparatively few, which can be cured at once by large depletions, and is sure that considerable danger to the existence of the patient would often be incurred if such a practice were

generally pursued. At the same time he is equally convinced of the propriety of moderate detractions of blood, as advised by Cullen, Haslam, and Foville. This remedy ought by no means to be neglected in cases of madness which have come on rather suddenly and with acute symptoms, unless some circumstance in the age, habit, or temporary condition of the patient, renders it unsafe. It is especially called for in young and in plethoric subjects; when the disease is one of great excitement; when there is constant agitation and want of sleep, and in such cases it should be adopted before these causes have induced exhaustion and collapse; when there are marks of determination to the head, such as full and throbbing carotids and temporal arteries, redness of the face and conjunctiva, heat of the scalp, a contracted pupil, intolerance of light or of sounds, headach, vertigo, startings, agitations, or convulsions. We are not to look for an aggregate of these symptoms before we prescribe bleeding, but more or fewer of them often occur to direct our proceedings. Less frequently we find the still stronger indications of which even M. Esquirol allows the force as pointing out the necessity of bleeding. We allude to the circumstance that the disease has arisen from the sudden suppression of catamenia or of some morbid but, perhaps, also salutary discharge, from the disappearance of eruptions, or from the operation of powerfully exciting causes. Among these is the abuse of stimulating liquors. Madness, which is the effect of intoxication, requires antiphlogistic remedies, and bleeding cannot be dispensed with; but care must be taken not to carry depletion too far in cases arising from this cause which assume in some degree the character of delirium tremens. We have reason to believe that patients labouring under delirium tremens have been killed almost instantaneously by large bleedings, which had been ordered by practitioners who were unaware of the nature of the case. This, however, is a form of disease easily distinguishable from ordinary madness resulting from intoxication. It is frequently advisable to bleed once or twice from the arm to the extent of fourteen or sixteen ounces, and afterwards, if the indicatory symptoms continue, to apply cupping-glasses to the scalp, after it has been shaved, and repeat this operation or the application of leeches as often as the degree of excitement and signs of vascular fullness, the circumstances of the patient otherwise admitting, seem to require.

Many practical writers have insisted on the necessity of bleeding in the early stage of madness, without advertent to the important advantages which are to be derived from the same remedy in the after periods of the disease. These, however, are highly important. The practice of bleeding to a small extent, either from the arm, or, what is commonly preferable, by cupping-glasses applied to the scalp or the nape of the neck, and repeating the operation in some instances periodically when the tenor of symptoms has been nearly uniform, or

occasionally when the patient has been subject to fits of increased excitement, has appeared conducive to ultimate recovery in a great number of instances. When suppression of the catamenia or of hemorrhoidal evacuations have preceded the attack, cupping on the sacrum or the application of leeches to the hemorrhoidal vessels may perhaps best supply the defect of the natural or habitual method of relief.

The other resources, which are comprised under the antiphlogistic treatment of madness, will require a much less extensive consideration.

Shaving the head should always be done when there is much vascular excitement and heat about the scalp. By the coolness afforded on the removal of the hair, more benefit and a greater degree of tranquillization is often produced than is anticipated. Cutting the hair short is not sufficient: the head should be shaved once or twice in a week.

Blisters, setons, caustics, irritants of various descriptions, have been applied to the head and the nape of the neck in cases of madness, as well as in other diseases of the brain.

While acute symptoms are present, with heat of the head and irritation of the general system, cold applications are preferable to blisters; but when these indications are not prominent, and when there is rather a tendency to stupor than excitement, blisters on the head are frequently of service. They have been applied in most cases to the nape of the neck with some advantage, particularly when, as it has often happened, the discharge which follows their application has been very considerable.

M. Esquirol has remarked that blisters, cuppings, and other irritating applications, are used successfully in cases which follow a metastasis; in monomania accompanied by stupor; in puerperal madness; and in dementia when not complicated with convulsions or paralysis.

Issues and setons in the neck have been often tried, but the general result of experience is not favourable to their use. They afford little benefit in maniacal cases. In dementia connected with paralytic affections, they are more likely to be of service than in mania attended with excitement. In the ordinary chronic state of madness, these remedies are found to be rather injurious than beneficial.

Irritating ointments have been applied in many instances, particularly since their use was strongly recommended by the late Dr. Jenner. Medical practitioners have been generally disappointed in their expectation of benefit from this attempt. It is most likely to be successful, as hinted by M. Esquirol, in cases of metastasis.

Cold water and bathing.—Cold shower-baths, and affusions of cold water administered in various methods, have been extensively tried in maniacal diseases. Dr. Rush considered them to constitute a very important remedy, and recommended, in order to obtain the

greatest advantage from them, that they should be repeated two or three times in a day. M. Esquirol used this remedy with advantage in some cases; he chiefly prescribed it for young subjects. M. Foville says that he was a witness to an almost immediate cure of a maniacal girl of delicate constitution and nervous temperament, who was subjected by M. Esquirol to the affusion of cold water at the degree fourteen of the centigrade thermometer. She was placed, with a garment covering her, in an empty bathing-tub, and water was poured in small quantities on her head till it covered her body, and shivering ensued. On a second application of this method, which was for some time resisted, it was followed by deep sleep, accompanied by copious sweating; and when the patient awoke, she was found to have recovered her reason.

The method of bathing adopted by M. Foville in the hospital under his management is free from the inconveniences and occasionally injurious results attendant on cold affusions. He places a cap or bonnet, containing ice and closely fitting, on the head of the patient, and keeps the body immersed in a warm-bath for two or three hours, and renews this proceeding twice or three times in a day, according to the intensity of symptoms. On adopting it, as he was accustomed to do at first, only once in a day, he found the tranquillity produced by it followed not unfrequently by increased agitation; but on repeating the bath, with the ice constantly applied to the head, he has frequently succeeded far beyond his expectation. It has been the apparent means of recovery in many acute cases, and has produced sleep and tranquillity in frequent instances of obstinate restlessness and agitation.

The use of the shower-bath is often followed by reaction, when the patient, if excitable, becomes violent. In old cases, attended with a disposition to congestion of blood in the head, its use is precluded by the danger of producing paralysis. It is chiefly serviceable in young subjects; when the constitution is relaxed, and when it is predisposed to hysteric affections.

Applications of ice, or, when more convenient, of cold water, are very generally serviceable in cases attended with heat of the head and irritability.

Warm or tepid bathing has been found advantageous in the treatment of madness under a variety of circumstances. A cold state of the skin, languor of the general circulation, indicated by coldness of the extremities, a tendency to chronic eruptions, are among the phenomena which suggest its adoption. Sometimes it produces sleep after long-continued agitation. If the degree of heat be not such as to produce too much vascular excitement, it is generally an useful and safely applicable remedy.

Purgatives.—No fact in medical practice has been longer established than the utility of purgatives in madness; witness the fame of

Antieyra and hellebore. To confirm a maxim so well supported by the result of constant experience, it seems almost superfluous to adduce pathological facts. It is not, however, difficult to find this species of evidence in its favour. Many authors have remarked that spontaneous cure of madness has resulted from a supervening diarrhœa, in which the intestines have discharged in great quantities a variety of morbid secretions.

M. Esquirol has well observed that purgative medicines ought not to be used indiscriminately in all cases of madness, and that they are injurious when the mucous membrane of the intestinal canal is in a diseased state. This is the case in many instances of insanity. We shall, under another indication for medical treatment, consider the method of practice which is advisable in different states of intestinal irritation, as they occur in madness. At present it will be sufficient to observe that, unless any signs of disease exist in the structure of the alimentary canal, such as inflammation or ulceration of the mucous coat of the intestines, the use of purgative medicines is one of the most important and generally available means for the cure of maniacal patients. The mildest cathartics are preferable to others in most instances, because their use can be long continued without injury to the structures on which they immediately act. The neutral salts, infusion of senna, rhubarb, jalap, castor-oil, are in the majority of cases sufficiently powerful, and may be used daily or frequently according to circumstances. When there is decided tendency to constipation, or the alvine evacuations are morbid, calomel, scammony, colocynth, or croton oil, may be added, due attention being paid to the cautionary circumstance above pointed out.

Emetics.—Emetics have been strongly recommended by some practical writers. M. Esquirol says that he has found them useful in most cases of melancholy accompanied by a torpid state of the system. Dr. Rush considered them to be chiefly indicated in hypochondriasis, or lowness of spirits connected with dyspeptic disease. Haslam confirms their utility in cases attended with disorder of the stomach, merely with a view to the relief of that particular symptom, but he declares that, “after the administration of many thousand emetics to persons who were insane, but otherwise in good health, he never saw any benefit derived from their use.” “Perhaps no one,” he says, “has enjoyed a fairer opportunity of witnessing the effects of remedies for insane persons than myself; and when emetics are employed in Bethlem Hospital, they have the best chance of effecting all the relief they are competent to afford, as they are given by themselves, without the intervention of other medicines; and this course of emetics usually continues six weeks.” “It has been for many years the practice of Bethlem Hospital to administer to the curable patients four or five emetics in the spring of the year; but on consulting my book of cases,

I have not found that such patients have been particularly benefited by the use of this remedy. When the tartarized antimony given with this intention operated as a purgative, it generally produced beneficial effects.” The most strenuous advocate, in late times, for emetics in madness is Dr. Cox, whose work on that disease contains many excellent practical observations. This author goes so far as to say, that, “in almost every species and degree of maniacal complaints, from the slightest aberration of intellect that accompanies hypochondriasis, to the extreme of mania furibunda, emetics have proved a most valuable and efficacious remedy.” Dr. Wake, physician to the York Lunatic Asylum, has assured the writer of this article, that, after extensive experience in the use of different remedies on the patients of that hospital, he has found no other class of remedies so frequently efficacious as emetics.

The use of emetics in madness requires caution. Dr. Haslam says, that, “in many instances, and in some where bloodletting had been previously employed, paralytic affections have within a few hours supervened on the exhibition of an emetic, more especially where the patient has been of a full habit, and has had the appearance of an increased determination to the head.” As it is well established that lunatics are very subject to attacks of apoplexy and paralysis, this circumstance ought always to be taken into consideration in the prescribing of emetics to maniacal patients. The use of medicines of this class is precluded by the signs of a plethoric habit and cerebral congestion; but, as MM. Esquirol and Foville have well observed, they are likely to be of service, and this probability is confirmed by ample experience, in cases of melancholy or hypochondriacal dejection attended with stupor, and where the languid state of the functions, both animal and physical, appears to require the use of remedies which are fitted to excite new actions, and to stimulate the secretions of the abdominal viscera. It may be added that emetics are sometimes useful during a state of furious excitement, and produce calmness and a mitigation of violence. Sometimes under these circumstances their exhibition is followed by a restoration of sleep and tranquillity.

Maniacal patients often require large doses of tartarised antimony, as from six to ten grains, before vomiting is excited; and this is especially the case when the remedy is given during a paroxysm of violent excitement. It is, however, better to begin with moderate doses, and to combine ipecacuanha with the preparation of antimony.

The use of antimony in nauseating doses is always safe, and very frequently beneficial in controlling maniacal excitement and the febrile state of the system which accompanies it.

Rotation.—The use of a rotatory swing, which occasions vertigo and nausea, and if continued a sufficient time, brings on vomiting with some degree of faintness, was suggested, chiefly

from a theoretical notion, by Dr. Darwin. The beneficial effects of this remedy have been supported on the ground of experience by Dr. Cox. Some writers have ridiculed the idea of attempting such a remedy, and others have thought it difficult to imagine on what principle it can be of any service; but those practitioners who have put the proposal to the test of experiment have, if we are not mistaken, in most instances been convinced of its utility. Among these may be mentioned Dr. Wake of York, who has assured us that he has long considered the rotatory swing as a remedy of great efficacy. It was used by Dr. Cox in cases of violent maniacal excitement, and proved a powerful sedative. The nausea and sickness induced was found to quiet the patient and put a speedy termination to the paroxysm. It was not requisite in all cases to bring on vomiting. Quiet sleep often followed the use of this remedy.

The rotatory swing is also useful as a means of moral restraint. The effects are so disagreeable that the threat of repeating its use has a salutary influence upon turbulent and intractable patients.

2. *Second indication.*—The principle of medical treatment hitherto considered, which has respect to the physical condition of the brain in cases of maniacal disease, is chiefly applicable to the acute stage and early period of its duration. The pathological fact on which it in part is founded, may be usefully borne in mind in the subsequent progress of the complaint, and acted upon more or less when circumstances allow or require it, but it cannot, when the disorder has become confirmed, be the chief guide of the practitioner. The marks of determination to the head have generally, under such circumstances, in a great measure subsided. In these instances inflammatory action in the brain has probably given way to a state of relaxation bordering on serous effusion, or to other changes which imply rather the consequences than the existence of increased vascular action.

The second indication for the medical treatment of insanity, which has relation chiefly to the more advanced period and chronic aspect of such disease, is to restore and maintain, as far as it can be done, a healthy condition of the physical or natural functions, to obviate or remove disorders in other parts of the system, which may be connected or coincident with the diseased condition of the brain.

We have already observed that in a great proportion of maniacal cases there are symptoms of disturbance in the natural functions, and that diseases of the thoracic and abdominal viscera co-exist with that morbid state of the brain on which madness immediately depends;—that the former are in fact often the immediate causes of death. The relation in which these diseases stand to the cerebral disorder may be doubtful in many instances; in some it is the relation of cause, in others that of effect: even in the last instance there is a reaction of the secondary upon the primary parts in the series of morbid

changes, and the original disease is aggravated by its complication with an accessory one. By relieving the latter we obtain a proportional mitigation of the former. It is indeed a fact that many lunatics have been cured by a course of remedies adapted to the restoration of their general health. The writer of this article has often seen persons who had laboured for some months, or even years, under mental derangement, brought from poor-houses in the country, or from their private dwellings, in a state of emaciation and squalid wretchedness, suffering under various disorders which had become complicated with insanity, or had in some instances preceded it. These persons have been placed under medical treatment; care has been taken to relieve the symptoms of visceral disorder, to restore the functions to a healthy state, to afford them good and nutritious diet, and to remove complaints which occurred from time to time by occasional remedies. In many cases of this description, as the general health improved, the mental disorder has gradually lessened, and has finally disappeared. In the course of four, five, or six months from the period of their coming under medical treatment, very many patients of this description have been restored to their usual state of health, and to the exercise of their customary occupations, after having undergone the operation of few remedies except such as are adapted to the indication or principle of practice now pointed out.

The mode of treatment required in following this indication must vary according to the state of the constitution and the modifications of disease which particular cases may present.

In examples of madness complicated with intestinal disorder, care must be taken to relieve the latter by the various remedies and modes of diet and regimen which the disorder of the intestinal canal and its function require. A torpid state of bowels must be overcome by the use of mild aperients, continued daily, or given occasionally according to circumstances. When constipation has given way to diarrhoea, with tenderness, abdominal distention, with or without occasional symptoms of dysentery, with emaciation, coldness of the skin, general debility, a disposition to eruptions resembling those of scurvy or purpura, the cure can only be promoted by a careful attention to a variety of particulars. The action of the bowels should be restrained by absorbent medicines, combined with slight opiates and mercurial alteratives. The use of the warm bath, warm clothing, and a warm atmosphere, a mild and nutritious diet, should be enjoined at the same time. Bitters, vegetable tonics, and aromatics may be given to support the strength of the stomach and promote digestion: a liberal allowance of animal food, and sometimes malt liquors, and even a little wine are used with advantage in cases of debility and exhaustion when the digestive powers will bear their use.

When the actions of the intestinal canal are irregular in chronic cases of madness, without giving rise to so great a degree of disease as in the instances above indicated, a healthy state

of their function is sufficiently promoted by giving mild aperients, with bitter and neutral salts, two or three times in a week, and occasional doses of calomel.

When madness has been the result of, or has been accompanied by, diminution or loss of any other natural function or habitual process, an effort should be made to restore it. If we were possessed of any certain emmenagogue, it is highly probable that its successful application would in many cases promote the cure of maniacal diseases connected with the suppression of the catamenia. When habitual discharges from the hemorrhoidal veins have been coerced, or have ceased spontaneously, derangement of the health has ensued similar to that occasioned by uterine suppressions. The want of this latter process seems to be more easily supplied by the powers of art than that of the uterine function. M. Foville has mentioned a case which occurred to M. Esquirol, in which paralysis became complicated with madness in consequence of the suppression of an habitual hemorrhoidal discharge. The application of a single leech to the hemorrhoidal veins every day during a month was followed by a restoration of the flux, and the patient was cured of his complaint.

Attempts to restore the catamenia when defective in maniacal patients, as they very frequently are, seldom produce in a speedy manner the desired result. If any effort is perceptible at particular times to set up the periodical discharge, it should be promoted by small bleedings; by the application of leeches to the inguinal region or the thighs, or by cupping at the loins, together with the use of the hip-bath, pediluvium, general warmth of clothing and atmosphere, warm drinks, with doses of castor, camphor, and other odorous stimulants. At other times aloë, rhubarb, and aromatic bitters should be given daily by way of preparation.

Digitalis has been reckoned by some practitioners, particularly in Germany, as almost a specific in maniacal cases. Dr. Cox speaks favourably of its effects. By M. Foville its use is very judiciously limited to those instances in which disorder of the brain is coincident with, and, as he supposes, dependent upon disease, or at least increased action, of the heart, and particularly increased fulness and pulsation of the carotid and temporal arteries.

Opium and narcotics are *generally* injurious in madness. Their use is condemned by most practical writers. Occasionally, however, opium has been of decided benefit. Dr. Hodgkin has witnessed two cases of madness with a strong propensity to suicide, in both of which a strong dose of opium procured sound sleep, followed by a restoration of health. The use of opium requires great caution in maniacal diseases. No precise rules are determined by which we can judge of the propriety of its use.

The use of mercury has been highly recommended in madness by several writers, and particularly by Dr. Rush. Mercury is by no means a general remedy for maniacal diseases; but in cases of torpor, with suppression or a very scanty state

of any of the secretions, mercury is frequently employed with great advantage. It should be used in mild alterative doses, and discontinued as soon as the gums become slightly affected.

Attention to diet and regimen are fully as important for the fulfilment of the last-mentioned indication as any remedy whatever. In exhausted subjects, as before hinted, great advantage is obtained from the use of a liberal diet. A plentiful allowance of animal food of the most wholesome and digestible kind, with malt liquor, and in some instances a small portion of wine, is required. The adoption of a liberal diet is not only free in such cases from any exciting or too stimulant influence, but even appears to calm the irritation which previously existed. But no rule respecting diet can be laid down that must not be subject to modification in particular circumstances, and according to the peculiarity of the case and the state of the constitution.

Fresh air and exercise, for those patients who are in a condition that renders them fit for it, are among the most important restorative means. Every asylum for the reception of lunatics ought to be provided with the means of affording regular employment in the open air to all the patients who are able to undertake it. Gardening and various agricultural works should as much as possible occupy their time at stated periods of the day, and by system and judicious management a great majority among the inmates of these receptacles may be brought into the habit of devoting themselves mechanically to such employments. M. Esquirol remarks that the best effects have resulted from the employment of these methods. They are followed with the greatest advantage in several lunatic asylums, both public and private, in different parts of England.

Of the moral treatment of insanity.—We now proceed to the second division of the subject under consideration, viz. to the moral treatment of insanity.

The moral treatment of this disease has by many writers been made to include a variety of methods proposed with the hope of inducing, by an unexpected and powerful influence on the feelings of deranged persons, a salutary change in the state of their minds. These are either motives addressed to their passions, or a variety of ingenious schemes or stratagems for convincing them of the falsity of their hallucinations, and surprising them into a recognition of their erroneous impressions. It has been proposed to indulge the illusions of the insane to a certain degree in order to overcome their false notions by striking and undeniable proofs. We are told that a lunatic who fancied that he had a serpent in his stomach, was cured by giving him an emetic, and adroitly producing a reptile, as if it had been thrown up during the operation of the medicine. Even such writers as M. Pinel and M. Esquirol, otherwise so enlightened and so judicious, appear to lay some stress on attempts of this description. The latter had a patient who fancied that she had a little animal in her head: her

physician encouraged the idea, and proposed an operation; an incision was made on the scalp, and an insect produced: the patient was immediately cured. A lunatic mentioned by the same writer refused to eat; he had made a vow, and was bound in honour to abstain from food. After many days employed in the attempt to persuade him of his mistake, a pretended order was brought, signed by his sovereign, which commanded him to break through his resolution, and promised him a guarantee against any reproach on that account: after a moral struggle of some hours, he gave way with reluctance, took food, and was restored. Another individual, who had become insane in consequence of the political events of 1813, was informed of the revolution which occurred in the following year. He refused to believe. M. Esquirol led him into the midst of the foreign troops which surrounded Paris. He was convinced, and almost immediately cured.

It is barely within the sphere of possibility that a conjuncture may occur in the treatment of an insane person, when an attempt may be advisable to destroy his hallucination by some practical and striking proof; but, generally, attempts to convince lunatics that their impressions are false, and that they labour under mental disease, either by reasoning or by any contrivances, are abortive, if not injurious. The moral treatment which such cases actually require is of a very different kind.

The most important question which relates to the moral treatment of the insane turns upon the propriety of secluding them, and separating them from their families and from society. This is a subject which of late has excited much attention and serious consideration, both among medical practitioners and other persons in England. It has likewise been examined in every point of view by writers of just celebrity on the continent; M. Esquirol and M. Georget in particular have considered this subject in all its bearings, and have expressed their sentiments upon it with great perspicuity and soundness of judgment. We shall avoid all suspicion of prejudice or erroneous bias by citing the observations of these writers, whose authority will carry greater weight than that of most other individuals, removed as they have been from the influence of circumstances which have given rise to controversy and unreasonable varieties of opinion.

"The first question," says M. Esquirol, "that presents itself in connection with the moral treatment of lunatics, relates to their separation. Ought every insane person to be withdrawn from his accustomed habits, from his usual manner of living, separated from the persons with whom he habitually lives, to be removed into a place which is unknown to him, and confided to the care of strangers? All physicians, English, French, and German, agree upon the necessity and the utility of separation. Willis, to whom we have so long and with so much advantage resorted in England to obtain a cure in cases of insanity, has remarked that strangers were restored much more often than the English. We can make

a parallel observation in France. Cures are more frequent among the invalids who come to Paris to be treated there, than among those who reside in the capital. The latter have not been sufficiently isolated.

"The first effect of separation is to produce new sensations, by presenting new objects, and breaking the train of ideas which has laid hold on the mind; these new objects strike, arrest, and excite the attention of the lunatic, and he becomes more accessible to advice which may be the means of restoring him to reason. Thus the first moment in which a maniac is separated from his friends is always followed by a remission of the complaint, which is important for his physician, who, then finding the patient without prepossession, can more easily acquire his confidence.

"It is principally upon the disorder of the moral affections that the necessity of separation depends.

"The disturbed state, the exaltation of ideas of the insane patient, puts him in contradiction, not only with those who live with him, but even with himself. He persuades himself that his friends are determined to oppose him, because they do not agree with his excesses and extravagances. Not understanding what is said to him, he is impatient; generally he misinterprets the words that are addressed to him; proofs of the most tender affection are taken for reproaches, or for enigmas that he cannot understand; the most anxious cares are only intended to vex him; his heart cherishes only sentiments of defiance; he becomes timid and gloomy; he fears every one who approaches him; his suspicions extend to persons who had been most dear to him. The conviction that every person is intent upon opposing him, defaming him, rendering him miserable, destroying and ruining him, puts a completing stroke to this moral perversion." Thence arises that "symptomatic suspicion which increases under indispensable contradictions, which augments in strength as the intellectual faculties weaken, and which is painted so strongly upon the physiognomy of all insane patients."

"With these moral dispositions, if you leave an insane person in the midst of his family, the affectionate son, whose happiness consists in the society of his father, will soon desert the paternal roof. The despairing lover believes that he can, by his councils, bring back the wandering reason of her to whom he is devoted; he has the misfortune only to render the wound still deeper. The object of his affection soon sees in him only a perfidious traitor, who affects such eager anxiety the more easily to betray her. The tender and sincere friend hopes by affectionate cares to restore that sensibility and that reason which have been the source of his attachment and happiness. In a short time he will find himself included in the general proscription, and his cares will only appear to the afflicted person proofs that he has been corrupted by enemies. What hope can we entertain if we do not immediately change the situation of these

unfortunate persons, who are so strongly prepossessed? And who has not felt the difference that there is in being deceived, opposed, and betrayed by our nearest relations and friends, and by individuals who are altogether strangers and indifferent to us? Another unhappy person becomes, all at once, lord of the world, dictates his sovereign commands to all that surround him; he persuades himself that he is blindly obeyed by all those who have been accustomed to yield to his will through respect or affection. His wife, his children, his friends, his servants, are his subjects; they are all obedient, for how dare they be otherwise? He is in his own territory; his commands are despotic; he is ready to punish with the greatest severity whoever shall dare to make the least remonstrance. What he requires may be impossible—it is of no consequence: should the commands of the potentates of the earth meet with invincible obstacles? The affliction of his family, the chagrin of his friends, the anxiety of all, their deference to his will and caprices, the repugnance that each evinces to oppose him from the fear of exasperating his fury,—all contribute to confirm him in his silent possession of power and dominion. Withdraw him from his pretensions, transport him far from his house, from his empire,—removed from his subjects, surrounded by new scenes, he will collect his ideas, direct his attention to himself, and place himself on an equality with his companions.

“Very often the cause of mental derangement is to be found in domestic causes. The malady takes its rise from chagrins, from family dissensions, from reverses of fortune, from privations, &c.; and the presence of relations and friends increases the evil, often without their suspecting that they are the first cause of it. Sometimes an excess of tenderness seizes the patient; a husband persuades himself that he cannot make his wife happy; he forms the resolution of flying from her, and threatens to put an end to his existence, since it would be the only means of securing her happiness. Her tears, her melancholy countenance, are so many new reasons for persuading this unfortunate person that he can do nothing better than commit suicide.

“Sometimes the first commotion given to the moral and intellectual faculties has arisen in the home of the insane person, in the midst of his relations and friends. All these external circumstances being associated with the first attack and the disorder which followed, will often contribute to keep alive and foster the hallucination,—a phenomenon which easily explains itself, since ideas recur simultaneously with certain impressions, when these impressions and ideas have often been associated, or even when they have been connected, only once, but with remarkable force and energy. It is generally remarked that insane people feel an aversion towards certain individuals, without the possibility of diverting them from this feeling. The object of their hatred is almost invariably the person who before the attack possessed their tenderest affection;

hence it is that they are so indifferent to their relations, and oftentimes so dangerous; while, on the other hand, strangers are agreeable to them. The presence of strangers suspends the delirium of the insane, either by the influence of new impressions, which is always useful, or from a secret feeling of self-love, which induces lunatics to conceal their state of mind. I have seen patients appear quite calm before their physician and strangers, while they were at the same time abusing their relations or their friends in an under voice.

“Such are the obstacles and inconveniences that present themselves when patients are put under medical treatment, if they continue to live with their families; and such are the advantages that will accrue from their being placed in a house appropriated to their treatment, where they are surrounded by new circumstances and confided to the care of strangers.

“Under what circumstances ought they to be confided? We have already said that they ought to be placed in a house appropriated for the treatment of insane persons. We prefer such a house to a private one, where patients may be confined at a great expense. Such partial separations rarely succeed: they possess many of the inconveniences which it is desired to avoid in leaving patients in their own habitations, and they present very few of the advantages of a house destined to receive a number of individuals. The strongest objection against separation or the placing patients in a lunatic asylum, arises from the distress which it is feared the patient will suffer when he observes that he is surrounded by companions in affliction. I reply that, generally, this does no injury to the patient, that it is not an obstacle to the cure, and that it oftentimes contributes to promote recovery. It leads maniacal persons to reflect upon their own state; and while ordinary objects make no impression upon them, they are diverted by the extravagances of their associates. The presence of their companions may serve as a text to the practitioner who wishes to act upon their imagination. The weariness of confinement, the desire of being at liberty, the wish of seeing their relations and friends, are so many means of drawing their attention outwardly: to be occupied with what passes around them, and in some manner to forget themselves, is a step towards recovery. However, there are cases where separation, as all other useful things, may be injurious to patients, when it is not modified with reference to the susceptibility of the individual, the character of his delirium, his passions, his habits, his manner of living. We ought never to lay down absolute rules in practice; the art consists in skilfully discriminating the circumstances which ought to modify general principles, whatever confirmation they may have derived from experience.”

The preceding observations of M. Esquirol have been confirmed, and in some particulars more strongly stated, by the late M. Georget. This intelligent writer has remarked that all physicians who have habitually the care of

lunatics, have recommended the seclusion of these invalids, in almost every case, as the first condition, and one of the first means in their treatment. "Lunatics," he says, "ought to be separated from the objects which have excited their disease, or which foster or aggravate it; from relatives or servants whom they dislike, whom they pretend to command, and to whom they will never submit; from busybodies, who only irritate them by useless arguments or misplaced ridicule: they ought to be separated from society, and placed in an appropriate habitation, to ensure both the safety of the public and their own preservation. Their friends are always repugnant to put this plan into execution: a mother, a wife, or a husband; can with difficulty believe that the object dearest in the world to either of them can be better placed in the hands of strangers than under the influence of those who are eager to devote the most affectionate cares; they fear likewise that in lunatic asylums the sight of the patients will have a bad effect upon their friend, and aggravate the disease; that constraint, severity, and all kinds of bad treatment will be employed to manage the patients, and, if once cured, they will preserve a horrible impression of their abode, and resentment against their relations who have consented to their confinement. These last considerations induce rich families to place their deranged relatives in private houses destined to receive a single lunatic, who is surrounded by servants and inspectors whom he does not know. Besides that these private establishments are very expensive, they rarely answer the end proposed; either some relation chooses to remain near the invalid, or the latter soon perceives that every thing by which he is surrounded is destined for his service; in either case the objects of seclusion are imperfectly attained. Lastly, many things are often required which are only to be found in public establishments. This imperfect separation, however, is all that can be adopted in some families, and we must make as much advantage of it as we can. In public asylums the seclusion is complete; the patients soon know that they are under the authority and even at the discretion of the director; they are watched and constrained without difficulty, under the care of regular attendants. They find powerful sources of occupation and of distraction in associating even with the other patients. The greater number of lunatics never discover that they are in the midst of mad people, and find nothing to complain of in this circumstance. When their reason begins to return, they are removed into the department destined for the reception of convalescents, and hence are withdrawn from sights which might make unpleasant impressions upon them. As long as the disease continues, they are angry with those who have deprived them of their liberty; but as soon as they have recovered their reason, resentment is changed into gratitude. On this account, then, the friends of the insane incur no risk. We do not pretend to deny that this separation and abode among other lunatics has

occasionally aggravated the disease, when of recent occurrence, in some individuals: on the other hand, we affirm that the same means have cured many lunatics almost immediately. Besides it is next to impossible to preserve and take care of maniacs or monomaniacs in the midst of their family, and all the inconveniences of separation disappear under the absolute necessity of its use."

The same writer has briefly summed up the principal circumstances to which attention ought to be paid in the construction or choice and in the management of an asylum or house of recovery for lunatics. He has collected these remarks from the writings of Pinel and Esquirol.

"1. M. Pinel has particularly insisted upon the necessity of classing lunatics, of separating such as are liable to injure themselves or others, and permitting those to associate together who may contribute to each other's cure. A lunatic asylum ought, then, to be composed of several parts more or less insulated. There should be a quarter appropriated for each sex, a division for violent lunatics, a second for those that are tranquil, a third for convalescents, a fourth for lunatics who labour under accidental disorders. It will be very useful to have a division for those who are of melancholy habits, and in a state of dementia, and another for furious and noisy patients, and for some lunatics who are of an untameable character, and are confined by way of punishment. It is above all things necessary to separate the sexes, the convalescents, and likewise those patients who have depraved habits and indecent manners. Each division ought to have a court planted with trees, and, if possible, a garden for the patients to walk in.

"2. M. Esquirol, who has devoted his attention to the arrangements which these establishments require for the convenience of the patients, to facilitate vigilant superintendence and attention, and to prevent accidents, is of opinion that such houses should be built on level ground; that the cells destined for violent patients should be spacious, with a door and window opposite each other, and opening from without; that they should be boarded and not paved, furnished with a bed, firmly fixed in the wall; that all the cells should communicate with covered galleries or corridors, in which the patients may walk in bad weather, and by means of which the inspectors and servants may easily traverse the different parts of the establishment; that all the rooms should be warmed by pipes of hot air; that abundance of water should be furnished by fountains to wash the dirty cells; that the privies should be separated in such a manner as to occasion no inconvenience to the patients; that there should be places appointed for a general work-room, for a common dining-room, for baths and shower-baths. In this plan of M. Esquirol's there are dormitories only for convalescents, melancholic patients, idiots, and individuals who are debilitated. For others little cells with one bed are preferable, in almost every case; during the day the patients can go out and

associate with others, and in the night they do not require companions.

"3. Beings deprived of reason, who fancy themselves reasonable, who incessantly desire and demand things that cannot be granted them, and who are nevertheless sensible to kind as well as to bad treatment, must needs be difficult to influence, to govern, and to cure. As long as each person continues insane, he looks upon the director and inspectors of the establishment as accomplices in the power which has deprived him of liberty, and upon the attendants as inhuman jailors. Even after his cure he is not always very grateful. The director, the inspectors, and the attendants, will invariably be objects of prejudice, suspicion, and hatred to the patients; they will receive abuse and often blows from them. On the other hand, it is impossible for one who has not had for a long time the care of them, and studied their disease, to know the mental disposition of lunatics. Without such preparation we should attribute to wickedness what is the effect of disease, or look upon lunatics as beings deprived of all sensibility. In either case we might be induced to treat them with severity. It is almost impossible to make servants understand that mad persons have the use of some of their faculties, with the exception of those servants who have been themselves attacked by the disease. At the Salpêtrière and the Bicêtre great advantage is derived from employing persons who have been cured to take care of the patients. The physician of a lunatic asylum ought to be particularly careful to instruct the individuals who are to have the management of the patients.

"4. It is absolutely necessary that a judicious arrangement of authority and subordination be established in lunatic asylums, and that the physician be invested with a power superior to all with regard to every thing that concerns the patients."

The chief points on which the moral cure of madness turns are thus summed up by M. Georget.

"We may refer to three principal heads all the regulations that can be put in practice with reference to the discipline and exercise of the mental powers in lunatics. 1. Never to excite the ideas and passions of the patients upon the subject of their delirium. 2. Never directly to oppose their unreasonable ideas and opinions, either by argument, discussion, opposition, contradiction, or ridicule. 3. To fix their attention upon subjects foreign to their hallucination, and communicate to their minds new ideas and affections by means of different impressions.

"According to the first principle, we should withdraw the patient from the causes which have excited his madness, and even from objects which might recal these causes, or suggest any allusion to them. Lunatics attacked with religious melancholy should be deprived of their books of devotion; they should not be permitted to engage in offices of religion. Those who are tormented with sexual desires render these desires more imperious by gratify-

ing them; if they do not destroy their health. We ought never to flatter the chimeras of kings, of princes, of gods, of queens. We should never put the patients attacked with the same kind of insanity together, because they would talk incessantly of their conceits, and thus cause to each other a great deal of injury. Thus, as in other diseases, we ought to leave the over-excited part at rest.

"According to the second rule, we should never attempt to reason with lunatics in order to bring them to their senses, for their errors are necessarily connected with their disease. The most evident proofs are of no weight upon the mind of a lunatic. He will suspect that there are secret reasons for deceiving him. Discussion, opposition, contradiction, irritates the disease, and inspires defiance and hatred. In accordance with the third rule, we should make it a point to occupy the mind, and to direct it by different means, such as exercise, work, play, the society of other patients, sane persons presiding over them; by music, reading, conversation, the visits of friends, &c. We should oppose one passion to the ruling passion, and on some occasions excite the activity of feeling by strong emotions, by means of fear, or the sudden announcement of bad news. But these different means are applicable neither in every case nor at every period of the disease. It is in general very difficult to turn for any length of time the attention of the patients from the subject of their delirium; it is above all things difficult to engage them in occupations either of work or amusement. Very often the disorder of their minds is such that they are continually under the influence of their delirium; they exist in their illusions, and their attention is hardly arrested by the objects that surround them. Restoration to their friends should never take place until the convalescence of patients is perfectly established, and even then great precautions must be used to manage the first interview, to prepare the mind of the patient and of the relatives, and to fix the subject and length of their conversation.

"An active and constant inspection exercised over the patients and the attendants is very necessary in a lunatic asylum. Patients who evince a disposition to suicide should never be lost sight of for a single instant, whatever they may say or do to obtain their wish. It is often necessary to confine violent patients with the strait waistcoat. Those who are addicted to indecent practices,—a circumstance by no means infrequent,—should be restrained by similar means. Occasionally it is better to confine them by shackles on the legs, fastened down in an arm-chair, or shut up in their rooms, according to circumstances. The use of chains is almost entirely abandoned, and we are indebted to the noble efforts of our venerable Pinel for this improvement in the lot of lunatics." (It may be observed that M. Foville ascribes to the Quakers who have managed the "Retreat" the credit of having been the first to discard these inhuman instruments of restraint.) "At the time of the abolition of chains at Bicêtre, M. Pinel observed that the diminution of the

number of furious lunatics, and the accidents which they occasioned, was very remarkable. The only measures of punishment that ought to be put into practice are the strait waistcoat, seclusion in a cell, removal from one division to another, the shower-bath, and some occasional privations. A violent or wicked lunatic, who all at once puts on a menacing appearance, or even commits reprehensible actions, should be immediately surrounded by a number of attendants, approached and seized at the same time on all sides, particularly by those who are behind him. Sometimes great advantage has been found by suddenly enveloping the patient's head in a napkin, which completely bewilders him. In other cases, while persons placed before the patient endeavour to occupy his attention, others advancing from behind easily lay hold of and secure him.

SECT. VII.—*Puerperal madness.*

This term is chiefly and most correctly applied to a form of insanity incident to puerperal women. By some writers the same expression has been so extended in its meaning as to comprise that species of derangement peculiar to females who are debilitated by suckling, and which commences in general several months after child-birth.

Symptoms of insanity occasionally display themselves during pregnancy, and under circumstances which indicate that they are dependent on that state. These cases are rare in comparison with those which occur after delivery. M. Esquirol mentions the instance of a young woman of very sensitive habit who had attacks of madness on two occasions, each of which lasted fifteen days, having commenced immediately after conception. The same writer observes also that several women at the Salpêtrière have become maniacal during the time of their pregnancy.

Cases of puerperal madness properly so termed, that is, coming on after child-birth, are by no means infrequent. M. Esquirol has related that among 600 maniacal women at the Salpêtrière, there were 52 cases of this description. In another report by the same writer, there were 92 similar cases among 1119 insane females admitted during four years into the above-mentioned hospital. M. Esquirol is of opinion that the proportion is still greater in the higher classes of society, since out of 144 instances of mental disorder occurring in females of opulent families, the symptoms had displayed themselves, in 21, either soon after child-birth or during the period of lactation. Dr. Haslam enumerates 84 instances of puerperal mania in 1644 cases admitted at Bethlem. Dr. Rush, however, reckons only five such cases in seventy received into the hospital for lunatics in Philadelphia.

There is no peculiarity in the phenomena of puerperal madness by which this disease is distinguished from other examples of insanity. Dr. Gooch has remarked that "if a physician was taken into the chamber of a patient whose mind had become deranged from lying-in or

nursing, he could not tell by the mere condition of the mind that the disease had originated in these causes."

Those cases which are more properly termed puerperal, as occurring in the first period after childbirth, are generally of the character of mania, attended with excitement of the feelings and mental illusions; while the disorder which displays itself in women exhausted by suckling is most commonly connected with melancholy depression, a tendency to which may generally be perceived in females who nurse their children too long with reference to the strength of their own constitutions. Cases of the former description occur within a short period, and most frequently within a fortnight after delivery. They appear sometimes to be occasioned by fright or other accidental causes of disturbance; sometimes by errors in diet, or by premature exertions or excitements: in other instances they take place independently of any discoverable external cause. The patient passes one or two restless nights, appears unusually excited and irritable, talks loudly and incessantly, and very soon betrays a disturbed intellect. The attack is often attended with febrile symptoms. This is the case especially, as Dr. Burrows has observed, if it takes place about the fourth or fifth day, when the secretion of milk is producing a new excitement. The state of the pulse is the most important symptom in reference to the nature and treatment of the case, as well as to the prognosis which is to be formed of its result. Dr. Gooch has laid particular stress on this circumstance, and he has extracted a valuable passage which bears upon it from the manuscript lectures of Dr. Hunter. "*Mania*," said this eminent practitioner, "is not an uncommon appearance in the course of the month, but of that species from which they generally recover. *When out of their senses, attended with fever, like paraphrenitis, they will in all probability die*; but when without fever it is not fatal, though it (i. e. fever) generally takes place before they get well. I have had several private patients, and have been called in when a great number of stimulating medicines and blisters have been administered, but they have gone on as at another time, talking nonsense, till the disease has gone off, and they have become sensible. It is a species of madness they generally recover from, but I know of nothing of any singular service in it."

Dr. Gooch's comment upon this passage is the remark, supported by his own observation, that there are two forms of puerperal mania: one of them is attended by fever, or rather by a rapid pulse; the other is accompanied by a very moderate disturbance of the circulation. Cases of the latter kind, which happily are by far the most numerous, terminate in recovery; the former are generally fatal.

Terminations of puerperal madness.—Puerperal madness terminates, in a great proportion of cases, either in death or in the recovery of reason. Few instances, comparatively, become cases of permanent insanity. It is, however,

very difficult to obtain accurate information on this subject. Dr. Gooch has observed that the records of hospitals contain chiefly accounts of cases which have been admitted because they had been unusually permanent, having already disappointed the hope, which is generally entertained and acted upon, of relief by private care: the cases of short duration, which last only a few days or weeks, and which form a large proportion, are totally overlooked or omitted in the inspection of hospital reports. This remark accounts for the unfavourable nature of the results which are obtained from such tables as those given by M. Esquirol and others. By this writer ninety-two cases are enumerated, of which fifty-five recovered, and six died, leaving thirty-one as the number of incurables, that is, one in three. Of the fifty-five recoveries, thirty-eight took place within the first six months. Dr. Haslam says that of eighty-five cases admitted at Bethlem, only fifty recovered, leaving thirty-five as the number of incurables. Dr. Burrows mentions fifty-seven cases, of which thirty-five recovered, and eleven remained uncured; of the recoveries, twenty-eight took place within the first six months. Dr. Gooch has remarked that these tables throw but little light upon the real proportions of recoveries, and present a prospect unnecessarily gloomy and discouraging. He adds, "Of the many patients about whom I have been consulted, I know only two who are now, after many years, disordered in mind, and of them one had already been so before her marriage."

The question, on the solution of which there is the greatest reason for anxiety in reference to any particular case of puerperal madness, is, whether it is likely to be fatal; because, if not fatal, there is great probability of ultimate recovery. The most satisfactory way of coming to a conclusion on this inquiry in any individual case, is by the prognostications which the particular symptoms afford, and on this subject we can add little to what has already been said. The principal danger which menaces life in cases of this description is a state of extreme debility; the excitement of the vascular as well as of the cerebral functions, is so great as to wear out the strength, already at a low ebb, and neither recruited by nutrition nor by sleep, and the patient sinks from exhaustion. Experience has proved that a rapid circulation is the principal circumstance which tends to bring on this state. A very frequent pulse is the most unfavourable symptom. Long-continued resistance to sleep, and a state of complete restlessness, and the appearance of great weakness and inanition, give likewise reason for apprehension. If these signs are not found, the mental derangement of the patient need not give occasion to very serious alarm.

Medical authors have sought to found a prognostic in puerperal madness on the estimate of the proportions which deaths bear to recoveries. This cannot afford evidence on which so much reliance may be placed as on the symptoms of individual cases. Out of the

ninety-two cases mentioned by M. Esquirol, of which fifty-five terminated in recovery, there were, as we have observed, six deaths, and in Dr. Burrows's table of fifty-seven cases there were ten deaths. The former calculation gives one death in fifteen cases, and the latter one in six. But the patients in the Salpêtrière are probably removed thither after the period in which the disease is most dangerous to life. There must have been some circumstance tending to explain the discrepancy in the above-mentioned results. The proportion of deaths given by M. Esquirol's table may be somewhat too low, but we are inclined to believe that the result afforded by that of Dr. Burrows gives a greater mortality than the average number afforded by general experience.

Pathology of puerperal madness.—The pathology of this disease involves several disputed questions, which we must not pass over without stating them, although we by no means expect to furnish a solution that shall be satisfactory to all parties.

The first inquiry is whether puerperal madness depends for its immediate or proximate cause on inflammation of the brain and its membranes.

The arguments urged in proof of this opinion, are, in the first place, the result of anatomical examination in cases of madness in general. We must refer to a former section of this treatise on the necroscopical researches into the state of the brain in the bodies of maniacal patients, for evidence on this subject, and for proofs of the general inference that inflammation, or a state closely allied to inflammation, is really the condition of the brain in cases of insanity. As puerperal madness is identified by its symptoms with other forms of insanity, this analogical argument has evidently some weight until it shall be proved that this particular form of mental derangement furnishes an exception to the general fact.

Secondly, the phenomena displayed by dissections in cases of puerperal madness itself, have been thought by some to afford evidence in favour of the same conclusion. Unfortunately there is some discrepancy in the results of anatomical researches in respect to such cases. We have no extensive record of accurately related dissections, which might illustrate on a large scale the pathology of this disease. M. Esquirol says that he has examined the bodies of several patients who have died under puerperal mania, without being able to detect any morbid traces that pointed out the seat of the disease; and Dr. Gooch has given the details of a case, at the termination of which he says, in general terms, that although the body was examined by a very eminent anatomist, no vestiges of disease were discovered in the brain or elsewhere. In several other cases, however, described by the same eminent writer, it must be observed, that although the complaint had occurred in bodies already exanguious from uterine hemorrhage and other exhausting causes, there were discovered on dissection thickenings of the dura and pia mater, sinuses

full of blood, serum effused under the arachnoid membrane, hardness of the brain, and numerous bloody points, on cutting the substance of the hemispheres. Dr. Burrows has likewise referred to several cases in which there were marks of cerebral congestion; and in particular to one of Newman's dissections, in which the arachnoid membrane was quite firm, and nearly as thick as the dura mater. On the whole there is sufficient evidence that in general the brain of puerperal maniacs displays, in a greater or less degree, the phenomena which are accounted to indicate the presence of inflammation.

The reasons which in the minds of some writers have over-weighed all the arguments furnished by these observations, are the following: first, that the disorder in question frequently attacks patients who are previously in a state of great exhaustion, and therefore thought unlikely to be assailed by complaints of an inflammatory nature; and secondly, that puerperal madness, as might be expected from the circumstances under which it takes its rise, and the exhausted and debilitated state of many patients who are attacked by it, cannot be safely treated by powerful antiphlogistic measures, such as copious bleeding. "Are we," says Dr. Gooch, "to shut our eyes to the symptoms during life, to the effect produced by remedies, to the mode in which death comes on,—that is, with symptoms of exhaustion, and to the remarkable emptiness of the veins throughout the body; and because there was a little serum under the tunica arachnoides, and more bloody points than usual in the medullary substance of the brain, conclude that it was a disease of congestion or inflammation, and that perhaps the patient died because she was not bled sufficiently?" This last part of the inference would, indeed, be much more than the premises would warrant; the question, what is, in a pathological point of view, the condition of the brain, becomes comparatively unimportant and almost a matter of mere curiosity, when the practical indications are already given, and even become the data from which we are to deduce reasons as to the nature of the disease. Yet it must be allowed that the existence of inflammation is not disproved by either of the arguments advanced. The disease supervenes on an exhausted state of the system, but so do many other inflammatory complaints. Pneumonic affections often attack women who have suffered much in childbirth from uterine hemorrhage, but we do not for this reason call into question the inflammatory nature of pneumonia. Neither are we authorized in asserting that the disorder is not inflammatory, by the fact that the patients labouring under it do not bear bleeding *ad libitum*. How many inflammatory complaints are there in which we cannot venture freely on the use of the lancet? Dr. Gooch's observation is, in a practical point of view, of the highest value. Antiphlogistic and evacuant remedies must not be used without the greatest caution in cases of puerperal mad-

ness; but the existence of inflammation in the brain and its membranes, when evidence of it is displayed in the characteristics of vascular fulness and other usual phenomena, is not disproved by this consideration.

The theory of this disease, in reference to the nature of its constitutional and proximate causes, may be different in cases which occur at different periods; and this is the more likely, because these cases vary in respect to their phenomena.

In those instances of maniacal affection which occur during pregnancy, it is probable that the disordered state of the brain or of the cerebral functions is the result of sympathetic excitement, which the vascular system, perhaps that of the brain in particular, sustains from the peculiar state of the uterine functions. The well-known complaints connected with temporary excitement of the brain in some females at the period of the catamenia, the symptoms thence resulting, such as the returns of hysterical, epileptic, cataleptic paroxysms, or of hysterical and sometimes maniacal excitement of the mind, are pathological facts sufficiently illustrative of the affection alluded to, and shew it to be in accordance with other morbid phenomena.

When madness comes on after childbirth, the pathology of the case is, perhaps, different from that of the affection now described. Dr. Gooch said, "the cause of puerperal mania is that peculiar state of the sexual system which occurs after delivery." He afterwards thought this account of the matter not sufficiently explicit. "What I meant was this; the sexual system in women is a set of organs which are in action only during half the natural life of the individual, and even during this half they are in action only at intervals. During these intervals of action they diffuse an unusual excitement throughout the nervous system,—witness the hysteric affections of puberty, the nervous susceptibility which occurs during every menstrual period, the nervous affections of breeding, and the nervous susceptibility of lying-in women. I do not mean that these appearances are to be observed in every instance of puberty, menstruation, pregnancy, and childbirth, but that they occur sufficiently often to shew that these states are liable to produce these conditions of the nervous system." He adds, "Dr. Marshall Hall thinks that the susceptibility of the puerperal state is to be explained by mere exhaustion, and does not at all depend on the influence of any thing specific in the condition of the several organs at that time; but would an equal or a greater degree of exhaustion at any time occasion the disease? This is a question of fact which I should answer in the negative. I have seen patients who have been deranged in childbed, and who had recovered, at a future period much more exhausted by illness, and much more agitated in mind, without the slightest appearance of mental derangement."

It would seem that we are here referred for an explanation of the maniacal affection which

occurs soon after childbirth, to excitement produced by the state of the uterine system. A remark, however, which obviously suggests itself on this subject is, that the phenomena of puerperal madness usually display themselves just at the period when uterine excitement is subsiding. If ever the uterine functions, or the activity of the whole system of organs connected with them, is suspended, it is during the time shortly following the puerperal period. We should not, at this conjuncture, expect the brain and the mind to be excited by sympathy with organic actions, which are in fact in a state of temporary cessation. But the expression, excitement of the sexual system, which is allowed to be too indefinite to convey a very precise meaning, may include the process of lactation. Perhaps it is to the irritation produced by the secretion of milk that we are more particularly to direct our attention; for this secretion is a part of the series of functions belonging to the sexual system. But here we only return to the popular notion, according to which the disorder depends on the flow of the milk. Such is the opinion of old women and nurses in general, and it may be the true one. The relations, however, of puerperal madness to the different processes which are set up or cease in the animal economy subsequently to childbirth, will be illustrated, if susceptible of illustration, by an exact observance of the periods at which this affection most frequently displays itself. The information obtained on this subject is not so complete as we might desire, but still it is of some value.

Sauvages and other writers have recognized two different forms of mental derangement incident to lying-in women. One of them has been termed "*paraphrosyne puerperarum*," and is observed to succeed labour, immediately or within a day or two, before the secretion of milk can disturb the system, and independently of any lochial suppression. "These attacks," says Dr. Burrows, who assents to the above distinction of varieties in the disease, "will sometimes go off under the operation of a smart purge and an opiate, and may then be considered as merely accessions of delirium; in other instances they are more permanent, and become fully developed instances of puerperal insanity. Sauvages' second species is termed '*mania lactea*;' and Dr. Burrows is of opinion that maniacal symptoms in reality make their appearance most frequently about the third or fourth day after childbirth, which countenances the notion that they are connected with the lacteal secretion. This writer, however, has very candidly referred to the evidence deducible from the tables published by M. Esquirol, although it is rather opposed to the opinion above stated. From these tables it appears that in the years 1811, 1812, 1813, 1814, eleven hundred and nineteen insane women were admitted into the Salpêtrière, of whom ninety-two laboured under puerperal madness: of these—

16 became delirious from the first to the fourth day.

21 from the fifth to the fifteenth day, which generally includes the termination of the lochia.
17 from the sixteenth to the sixtieth day.
19 from the sixtieth to the twelfth month of lactation.

19 after forced or voluntary weaning.

The result seems to be, as Dr. Burrows allows, that the disease is more frequently a consequence of delivery than of suckling.

On the whole it appears evident that some cause more general in its influence than any one particular process must be referred to, if we would explain the frequent occurrence of madness in pregnant, puerperal, and suckling females.

A view of this subject which seems to us more illustrative of it, occurred to Dr. Ferriar, and has been thus stated by him.

"I am inclined to consider the puerperal mania as a case of conversion. During gestation, and after delivery, when the milk begins to flow, the balance of the circulation is so greatly disturbed as to be liable to much disorder from the application of any exciting cause. If, therefore, cold affecting the head, violent noises, want of sleep, or uneasy thoughts, distress a puerperal patient before the determination of blood to the breasts is regularly made, the impetus may be readily converted to the head, and produce either hysteria or insanity, according to its force and the nature of the occasional cause."

That new determinations in the vascular system should ensue on the removal of one so long subsisting as that to the uterus during pregnancy, is in accordance with a well ascertained principle in pathology. The natural and healthy determination under these circumstances is to the lacteal glands, but owing to various causes, either external or of predisposition, morbid determinations occasionally take place. Some women become phthisical at a very early period after childbirth, or rather the symptoms of phthisis develop themselves at that time in a manifest form. Other constitutional complaints are apt to arise at the same period, according to the prevalent tendency of the habit. When the brain is susceptible, it is likely to suffer in its turn, and become the seat of local disorder, the manifestations of which are affections of the mind. If we consider the frequent changes or disturbances occurring in the balance of the circulation from the varying and quickly succeeding processes which are carried on in the system during and soon after the periods of pregnancy and childbirth, we shall be at no loss to discover circumstances under which a susceptible constitution is likely to suffer. The conversions or successive changes in the temporary local determinations of blood which the constitution under such circumstances sustains and requires, appear sufficiently to account for the morbid susceptibility of the brain.

The cases of mental disorder which occur in the later periods of lactation are, as it is evident from M. Esquirol's table, of two kinds. In one the disease supervenes on

weaning, and probably has its origin in the subsidence of the lacteal secretion. There are other instances which appear to arise from the continued excitement and exhaustion of the system consequent on suckling. This state of exhaustion takes place at different periods in different constitutions. Some women can continue to give milk without injury for years, but by others, morbid feelings are experienced in the space of a few months or even of as many weeks, and do not subside for some time after weaning. The writer of this article has observed very numerous instances of melancholy dejection with symptoms of insanity more or less strongly marked, which have displayed themselves in the protracted period of nursing, and in females who were evidently suffering from exhaustion. In one instance a lady, who on former occasions had complained of feelings termed nervous, and had been much indisposed when giving milk, was persuaded to continue suckling a child until the thirteenth or fourteenth month. She was then attacked by a maniacal disorder, which, though of a mild character, was very decided in its nature. Nearly a year passed before her mind was perfectly restored.

Treatment of puerperal madness.—If we consider that the greatest danger to be apprehended for patients labouring under puerperal madness arises from a state of extreme exhaustion, that many women die from this cause within a short interval from the commencement of the disease, and that if they survive this period, the healthy state of the mind is in most instances restored, it will be evident that our chief endeavours must be directed to the present support of life. If we can maintain and restore the general health, and keep the natural functions in a state compatible with continued existence for a time, the disease of the animal system will in all probability subside. Antiphlogistic and particularly evacuant remedies must be used very sparingly and with great caution.

1. Bloodletting, as a general remedy for puerperal madness, is condemned by all practical writers on whose judgement much reliance ought to be placed. M. Esquirol is decidedly opposed to it. Dr. Gooch's observations on this subject contain the best exposition of the rules which ought to guide medical practitioners as to the use of the lancet in cases of puerperal madness. He says, "The result of my experience is, that in puerperal mania and melancholia, and also in those cases which more resemble delirium tremens, bloodletting is not only seldom or never necessary, but generally almost always pernicious. I do not say that cases never occur which require this remedy; no man's experience extends to all the possibilities of disease, but I have never met with such cases, and I would lay down this rule for the employment of bloodletting—never to use it as a remedy for disorder in the mind, unless that disorder is accompanied by symptoms of congestion or inflammation of the brain, such as would lead to its employment though the mind was not disordered. Even

here, however, great caution is necessary; local is safer than general bleeding. In one case the head was hot, and the face red, and the pulse was said to have become somewhat hard, yet a bleeding of eight ounces was followed by extinction of the pulse within three hours, and death in less than six. The only cases attended by a quick pulse which I have seen recover were those in which no blood was taken. In the really inflammatory diseases of the brain, bloodletting of course is essentially necessary, but these, I think, can never be mistaken for puerperal insanity; they are febrile headaches, more or less acute. Pain of the head with fever is a much better indication for bloodletting than disorder of the mind without these symptoms."

2. In cases attended with much heat about the scalp, flushing of the face, and strong pulsation of the temporal and carotid arteries, it will be proper to shave the head and keep it cool by means of cold lotions, or an oil-skin cap filled with ice or iced water, or by evaporating lotions. If the symptoms above mentioned and those of mental excitement are very acute, and the debility of the patient is not in an alarming degree, a few leeches may be applied with advantage. Blisters to the occiput or nape of the neck are often serviceable; they are much recommended by practical writers. When the scalp is not hot, and the tendency of the disease is rather to stupor than to a high degree of excitement, blisters are usefully applied over the top of the head.

The lower extremities, which are often cold, should be frequently immersed in hot water, or a hip-bath used. Dr. Burrows recommends bathing the legs and feet in a warm infusion of mustard or horse-radish. Heat should be applied in the most convenient form, and the circulation in the extremities promoted by other obvious means.

3. Purgatives and emetics are among the most useful remedies in this disease. The alimentary canal is frequently in a disordered state, the tongue furred, the breath fetid, the skin discoloured, the evacuations dark and offensive. A few brisk purgative doses, calomel followed by castor-oil or rhubarb and magnesia, should be given in such cases. Emetics of ipecacuanha, with small doses of tartarized antimony, are very valuable remedies in this state of the alimentary canal. Dr. Gooch has remarked that they should be used with caution when the face is pale, the skin cold, and the pulse quick and weak; and in general he prefers ipecacuanha to antimonials.

4. After these evacuant remedies have been premised, great advantage is frequently derived from the use of opiates. Full doses are generally attended with the best success. Ten grains of Dover's powders may be given at night, or a grain and a half of solid opium, or thirty drops of the tincture. Several writers recommend Battley's solution of opium in preference to the tincture; perhaps the acetate and muriate of morphia are the best preparations of opium; they may be given in doses of a quarter or half of a grain, and repeated

every third or fourth hour until sleep is procured. When opiates disagree, Dr. Gooch recommends the use of hyoscyamus, mixed with camphor. He says that five grains of each should be given every sixth hour, and a double dose at night: a dram of the tincture will answer the same purpose. This writer is of opinion that narcotics are the most valuable remedy in the cure of puerperal mania; he says "that they often produce nights of better sleep and days of greater tranquillity, and this calmness is followed by some clearing up of the disorder of the mind." He says that these remedies produce salutary effects much more frequently in the mania of lying-in women than in maniacal disorders occurring under other circumstances; if, however, there is heat in the head, flushing in the face, and thirst, their use ought to be postponed until such symptoms shall have been removed.

5. In the more protracted cases of puerperal madness, tonic and stimulant medicines are sometimes requisite, especially when the appetite has failed. Ammonia is much recommended. It may be given with infusion of cinchona or any bitter infusion. When it is not offensive to the stomach, the rectified oil of turpentine is one of the best stimulants, especially if taken in the dose of a dram three times in a day with cinnamon water, or any other aromatic fluid.

6. A rule of great importance refers to the diet of women in puerperal madness. It may, perhaps, be safely asserted that the greatest risk which patients in this disease incur is that of being starved through the mistaken notions of their attendants, who are too often disposed to consider the excitement of maniacal disease a reason for withholding food, when this very state, owing to the exhaustion produced by its long continuance, renders it especially necessary to support the strength more carefully. Farinaceous fluids of a nutritive quality, milk, rice, and other such matters should be given at short intervals, when febrile symptoms preclude the use of animal food. In most instances broth may be allowed and ought to be given. In the more protracted periods solid meat, with malt liquors, should be taken. We have seen very many maniacal patients labouring under great weakness and exhaustion, with cold extremities, a clammy skin, passing sleepless nights, and under continual agitation, begin to improve as soon as their diet was changed, and meat with some ale or porter given daily. The pulse has become fuller and less frequent, the extremities warm, sleep has been restored, and convalescence has taken place in a surprisingly short period after such a system has been adopted.

7. The last observation to be made refers to the management of such patients. We must here advert to the remarks to be found in a former section on the management and moral treatment of maniacal patients in general. The general rules only require modification in some particulars in relation to the peculiar circumstances of puerperal patients. The latter for obvious reasons cannot be soon removed from

home. They require in other respects similar management. They should be separated from relatives and friends, and carefully attended by persons who are fitted for the occupation by habit. It will not so often be necessary to send puerperal maniacs to lunatic asylums as deranged persons of a different description.

SECT. VIII.—*Senile dementia.*

Senile dementia is essentially distinct from insanity; yet for various reasons that will be apparent, a short account of its phenomena will be properly introduced in this place.

We have already described that species of fatuity which is the frequent result of protracted insanity. The term dementia has been adopted by late writers to designate this morbid state of the mental faculties. This expression, however, has been used in a somewhat more extensive sense, as equivalent to fatuity in general, and as denoting, besides the ordinary sequel of madness, various other morbid conditions, in which the intellectual powers are impaired or obliterated. It is applied to the fatuity which occasionally follows apoplexy, epilepsy, palsy, and other comatose diseases. By many French authors the same term has also been made to comprehend the mental disease or decay peculiar to old age. In its last stage fatuity displays nearly the same phenomena in every case, by whatever causes induced or by whatever previous diseases it may have been ushered in; but in the early periods, to which, for reasons already explained, we purpose to limit the application of the term dementia, there are many shades of difference between its different forms. The intellectual weakness which follows apoplexy is not precisely of the same character as that demented state which is the sequel of insanity, and which occasionally gives way either to a renewal of maniacal excitement or to returning reason; nor is either of these affections precisely analogous to the decay of mind incident to old age. We must, in compliance with custom, continue to use the received term, but we shall distinguish the last-mentioned affection by the additional epithet of *senile dementia*.

The following is the description of dementia in general which has been given by M. Esquirol. "Dementia deprives men of the faculty of adequately perceiving objects, of seeing their relations, of comparing them, of preserving a complete recollection of them; whence results the impossibility of reasoning correctly. Demented persons are incapable of reasoning, because external objects make too feeble an impression upon them; because the organs of transmission have lost a part of their energy; or, lastly, because the brain itself has no longer sufficient strength to receive and retain the impression which is transmitted to it; hence it necessarily results that the sensations are feeble, obscure, incomplete: being unable to form a true and just idea of objects, these persons cannot compare them, or exercise abstraction or association of ideas; they are not capable of a sufficiently strong attention; the organ of thought has not energy enough: it has

been deprived of that vigour which is necessary for the integrity of its functions. Hence the most incongruous ideas succeed each other; independent of each other, they follow without order and connection; patients repeat words and entire sentences without attaching to them any precise meaning; they talk, without being conscious of what they say. It seems as if unreal expressions were heard by them in their heads, which they repeat in obedience to some involuntary or automatic impulse, the result of previous habits or of fortuitous association with objects which strike their senses."

Senile dementia differs in many particulars from the state of disease just described, though in some others resembling it. There is in both cases the same speedy and almost momentary obliteration of recent impressions, if the merely passive recognition of objects which present themselves to the senses may be so called. But in the disease peculiar to old age it may often be observed that ideas which were long ago stamped upon the mind remain with nearly their original force, and are capable of being called up whenever association suggests them, or the attention is purposely directed to them. The impressions produced by present objects are often so slight and evanescent, and the notions connected with them are so confused and indistinct, that the individual affected scarcely knows where he is; yet he recognizes without difficulty persons with whom he has long been acquainted, and if questioned respecting his former life and the transactions and pursuits of his youth or manhood, he will often give pertinent and sensible replies. The disorder of his mind consists not in defective memory of the past, but in the incapacity for attention and for receiving the influence of present external agencies, which, in a different state of the cerebral organization, would have produced an effect upon the sensorium, or seat of sensation and perception.

The following account briefly describes the state of a person labouring under senile dementia, who has been occasionally under the care of the writer of this article. It will serve to exemplify some of the foregoing remarks.

A. M——, aged about seventy years, was in his youth a farmer, but changed that occupation for the business of a baker, which he followed until he had accumulated property sufficient for his maintenance. He has been living for several years in retirement, and without any regular occupation. His memory is said to have undergone a gradual decay. When he is questioned respecting present objects and circumstances, he generally gives clear and distinct answers, but can seldom recollect what has occurred but a short time previously. In half an hour after he has been visited by his medical attendant, who is an intimate acquaintance, he will say, if asked, that he has not seen him for several days. His recollection of persons whom he knew in the former periods of his life, and of events which then happened to him, is tolerably clear, but at times, and especially after sleep, he does not know where he

now is. He sometimes fancies, at night, on waking from a short sleep, that he is engaged in his former occupations. He has risen from bed, and set himself busily to prepare for lighting a fire in his oven, beats the wall, calls his men up, and asks if the faggots are ready. He cannot be persuaded without great difficulty that he is in ——— street, and has nothing to do with the baking business. At other times he will get up in great haste to go down and see somebody who is waiting for him on business, or thinks that there is a horse standing for him at the door, calls for his clothes, and wonders that his friends are so tardy in assisting him. At these periods his state is not that of ordinary somnambulism. He sees and knows some at least of the persons who are about him, and will converse with them. He sometimes, during the day-time, wonders where he is, does not know the place though he has resided in the same house for some years. The hostess, who is an old acquaintance, at length convinces him that he is at her home. When his recollection is roused, and his thoughts are drawn into the right channel, he has a correct knowledge of persons, and shews not the slightest trace of maniacal illusions, or of anything approaching to the character of insanity. He is glad to see his old friends, shakes hands with them in his wonted cordial manner, is on the best terms with his relatives, and never displays the least deviation from the natural and habitual state of his feelings and affections.

Senile dementia, or the decay of the mental faculties, is not the lot of old persons universally, though it is a condition to which old age may be said to have tendency, and to which in the last stage of bodily decay some approximations are generally to be perceived. The change which time alone will perhaps sooner or later bring on, in those who long survive the allotted duration of man's days, may be accelerated by a variety of circumstances. Among these is a life of too much activity and excitement, of mental exertion beyond what the constitutional strength of the individual is capable of supporting without constant effort; excessive anxiety and eagerness in the pursuit of business, or intense and unremitted application to studies of whatever kind. The minds and bodies of men are only fitted for exertion in certain degrees, which, however, differ in different individuals; but the powers of all are limited. All have need of occasional respite from labour, and the appointment of rest during one day in seven is, from physical considerations alone, calculated to promote the well-being of individuals and of society. We may observe that among those who neglect this ordinance, there have been many who have suffered the penalty in this life. Some have terminated a rapid and perhaps brilliant career of unremitting and successful exertions by suicidal madness, of which too many and too well-known examples might be cited; others, though in a longer measure of time, have accelerated the period of intellectual decay.

A second cause of senile dementia, next in the frequency of its operation to that which we have

just mentioned, is the too liberal use of vinous or other fermented liquors. There are many persons who lead active lives, who are not considered intemperate, yet drink on an average nearly a bottle of wine in a day. Such persons, if their lives are not shortened, have every reason to expect a premature imbecility. The same affection has been observed frequently to make its appearance in men long engaged in active pursuits, soon after they have relinquished their business or professions, and have laid themselves by to enjoy ease and leisure for the remainder of their days. The disease often appears in a more marked and sudden manner in elderly persons who have sustained a slight attack of apoplexy or paralysis, which has perhaps been speedily recovered, and expected to have left but slight traces of disease. That expectation is verified so far as the sensitive and motive powers are concerned, but the seat of intellect is found to have been shaken in its very centre.

Senile dementia is entirely distinct from that species of moral insanity which appears occasionally, as we have already observed, in aged persons. The former is merely a loss of energy in some of the intellectual operations. It brings with it nothing morbid or unusual in the state of the feelings or affections, no tendency to depraved or unaccustomed habits; nor, commonly, any change in the temper and general disposition of mind. Individuals to whose lot this complaint has fallen are seldom unhappy on account of it, and if they are in any degree aware of their condition, they bear it with patience and cheerfulness. The state of the affections remaining natural and unperverted, is indeed a general diagnostic between disorders consisting merely of impaired faculties, and the forms of madness. The reverse of the previous remark applies, as we have said in the former part of this treatise, to the various modifications of insanity, and probably in greater or less degree to every case which can with perfect propriety be designated by that term.

This last observation, in its reference to senile dementia, may suggest a hint as to the justice and propriety of certain proceedings which are occasionally attempted and put in force with persons labouring under that affliction. As madness not only disorders the intellect, but likewise perverts the moral habits and the natural feelings of the afflicted individuals who are victims to it, there arises hence an obvious and unquestionable propriety in putting them under restraint. They are then not only placed under circumstances more favourable and sometimes essential to the cure of their complaint, but are likewise prevented from committing acts dangerous to themselves and others, and such as the same individuals would perhaps have shuddered to reflect upon in the days of sane and unclouded reason. To act otherwise with them would indeed be the height of cruelty. But the case is widely different when the moral disposition and the entire mental character remain unimpaired, and the memory only fails, or the aptitude to intel-

lectual exertion alone is diminished through the weakness of years. If an old man, who has spent the greatest portion of his life in active exertion, and has accumulated property by habits of labour and parsimony, after some time passed in retirement, begins to lose his recollection of passing events; if his faculties become impaired to a certain degree on account of that wealth which it has been the object of his life to accumulate, and for the amassing of which he has sacrificed all thoughts of ease and comfort during many successive years, he may now become the object of attack to some relative who may procure declarations of his incompetency to manage his estate. If such a person is brought before a jury and sharply interrogated, examined in figures, and puzzled by a variety of questions respecting matters of business, and other topics requiring accuracy in dates and calculations, it is not impossible that the affair may issue in his confinement in a lunatic asylum, or that at all events the management of his person and his affairs may be taken from the care of those to whom in the sound and entire state of his faculties he had confided both, and to whom, his moral affections and social feelings remaining yet unchanged, he still continues to be devotedly attached.

In France it has been for many years not unusual to confine aged persons of impaired faculties in the public *hospices* where deranged persons are admitted; and this practice has so much prevailed, that M. Georget alludes to it as a source of error and embarrassment in the attempt to determine the relative frequency of madness in late and in former times; these asylums being partly occupied by a number of old persons who remain till their decease, and whose disorders are not properly cases of insanity. Previously to the year 1790, out of 411 persons admitted as labouring under disordered or decayed intellect, there were only 19 whose age exceeded fifty years, whereas, in 2451 admitted between 1814 and 1821, not less than 880, or the third part of the entire number, were persons who had passed the period of life above mentioned. Of these, a great proportion were probably cases of senile decay. If the custom of thus getting rid of aged parents were a matter of choice and in general practice, without excuse on the ground of necessity, we might doubt whether our enlightened neighbours displayed their filial piety in a more advantageous manner than the *Battas*, who knock their aged relatives on the head and eat them, or than the old Irish, who, as Strabo assures us, *καλὸν τι ἡγοῦντο κατεσθίειν τοῖς πατέρας τελευτήσαντας*. But it is only among poor families that the custom prevails, and it is but parallel to the habit of the poor in England, who not unfrequently suffer their parents to die in parish workhouses. It is the greatest evil attendant on iron-handed necessity, that it so often breaks asunder the first and nearest bonds of duty and natural affection.

The following table will serve to illustrate the forms of disease which are included by medical writers under the common term of

dementia. It is styled by M. Esquirol, from whom we extract it, a table of causes. The table exhibits the distribution of 235 cases of dementia; the first column contains the number of patients admitted at the Salpêtrière during the years 1811 and 1812; the second column is the report of the author's private establishment, and is limited to persons of the higher or more opulent classes of society.

It may be remarked in reference to the first column, that the cases placed under the heads, 1, 2, 3, 8, 9, 12, 13, 14, 16, 18, 19, 20, 21, amounting altogether to 102, were probably instances of insanity in some of its forms, or of the stages of fatuity which are its consequences. There only remain 60 cases which, appear to have been instances of dementia not preceded by madness. Of this remainder, 46 cases are examples of senile decay, and these appear to form the great majority of cases, which are referred by the writer above cited to the head of idiopathic dementia, or dementia, unconnected with insanity. It therefore appears that this class of diseases nearly resolves itself into the sequelæ of madness, and the decay peculiar to old age.

It is obvious that the art of medicine in reference to senile dementia must be limited as to its sphere, in a great measure to the means of prevention, as cure is scarcely to be hoped. The prevention of this melancholy termination must, however, depend upon the habits of the individual, and on the mode in which the previous years of life may have been passed. In the regulation of previous habits may be found resources adequate in general to averting the approach of mental decay. Much will depend upon the manner of living during the early

period of old age, or when the physical powers are beginning to decline. Habits of indolence, and those of too great mental exertion, should be alike avoided; since many are observed to lose the vigour of their minds after a sudden and total retirement from active business, while in others the disordered state seems to have been brought on by too close application to studies, and particularly to those which require a sedentary life. The former of the causes above mentioned is, however, by far the most powerful and frequent in its operation, and numberless instances may be cited of persons who have exercised professions requiring considerable labour of mind during advanced years, without experiencing in consequence any decay of faculties.

The preservation of health in old age, both in other respects and in what regards the functions of the brain, will depend, in a very considerable degree, upon the adaptation of diet and regimen to the constitutional state of elderly persons. With the alteration of habits which advancing age implies, with the various changes in the state of the physical functions which it brings with it, a corresponding variation in diet and regimen is necessary, and if this is not made, disorder ensues. Many of the diseases incident to elderly persons are diseases of plethora, as apoplexies, and paralysis, and vertigo, and these are not unfrequently the preludes of dementia. The decay of faculties is observed to occur without such preludes in persons who live too freely. These and other considerations render it probable that the disorder of the brain connected with senile dementia depends upon a state of vascular repletion. When the disorders of old age have commenced, by a comparatively spare diet, consisting principally or entirely of farinaceous and other light vegetable food, by discontinuing in a great measure the use of wine and fermented liquors, the general health, and that of the brain in particular, will be greatly promoted. If there are decided threatenings of cerebral disease, an issue or seton, and the frequent use of mild aperient medicines to maintain a copious alvine discharge, will contribute to the same end, and will not only ward off attacks of apoplexy and palsy, but likewise lessen the tendency to senile dementia.

(J. C. Prichard.)

INTERMITTENT FEVER.—See FEVER.

IRRITATION.—It is remarkable that a term so commonly employed and so indispensable as this, should never have received a definite and generally acknowledged application. The agents and subjects, the causes and effects, the influences and phenomena of disease, have all indiscriminately passed under the name *irritation*, until the word has ceased to designate anything, and, “*vox et præterea nihil*,” is prostituted to pass off any obscure and unintelligible matter of pathology, for which more definite terms will give no quarter. If a case presents itself with bold and positive

features, such as pain, convulsion, delirium, palpitation, jarring pulse, and highly disordered function, but without certain characteristics of inflammation, it is distinguished by some as irritation; whilst others use irritation and inflammation almost as synonymous terms. If a person faints or dies under a surgical operation, or from a crushed limb, without hemorrhage, the result is ascribed to irritation: in another example, after the same accident, or the same operation, fever arises, and the patient dies in raving delirium; yet this is also termed *irritation*.

We do not venture to impugn the high authorities that have rendered the term conventionally applicable to such varied and opposite affections; but we would warn the student not to be misled, in his reading, by the etymology of the word; nor to suppose that in the extended application which it has received from various writers, irritation means anything more restricted than a class of morbid states of very considerable variety.

In further illustration of these remarks, and as an introduction to this subject, we shall extract some account of the views of *irritation* from the works of two distinguished writers, M. Broussais and Mr. Travers.

M. Broussais ("Examen des Doctrines Médicales," and "Histoire des Phlegmasies Chroniques,") bases his description of irritation on the particular physiological views which he entertains respecting the vital properties of animal structure. These properties he calls sensibility and contractility; they are possessed in various degrees by the different tissues, and may be locally increased by certain circumstances; such local exaltation always causing a diminution or depression of vitality in some other organ or system. This exaltation of vitality is accompanied by an excessive afflux or congestion of fluids to the part, and constitutes what M. Broussais throughout his writings designates as *irritation*. The causes or circumstances which produce irritation are of four kinds:—1. Excessive excitement by certain agents, called stimulants or irritants, directly applied; 2. sympathy with another irritated organ; 3. the absence of a stimulus which is habitual to the part; 4. repulsion of excitability from other part or parts.

One of the most remarkable features of this doctrine is, that irritation, when once formed in any part of the system, becomes a cause of irritation in other parts or systems; the influence being propagated by sympathy through the medium of the nerves. The phenomena of irritation vary according to the part which it affects, but the afflux of fluids, or active congestion, is common to all primary irritations, and this is prejudicial to the functions and regular nutrition of the part. The first seat of irritation is acknowledged to be in the nervous fibrils of the irritated part; and even in this stage irritation may be so intense as by means of the sympathetic effects on the system to cause death. But M. Broussais looks to the effects on the vascular system as the most important; and if he does not in his pathology

describe irritation as vascular universally, his therapeutics certainly imply this; accordingly the terms irritation and inflammation are used indiscriminately throughout his works. The irritation may be confined to the white vessels only, and then he designates it a *sub-inflammation*; but this, as well as what is generally understood by inflammation, is included under the general term irritation.

The increase of sensibility and contractility implied in irritation is sometimes shewn by pain, convulsion, &c., but it is not always directly manifest, and is frequently not so, when irritation has its seat in the viscera, where a system of nerves exists which do not transmit sensations to the sensorium. Frequently the sympathetic irritations are more manifest than the original one that excited them. These secondary irritations or sympathies are of two kinds, organic, and those of relation. The organic consist in organic phenomena, such as increased action, congestion, disordered secretion, nutrition, temperature, &c. Morbid sympathies of relation are shown by pain, convulsions of the voluntary muscles, and mental derangements. Any of these kinds of sympathy may be excited separately, but they more commonly co-exist; and in proportion to their intensity and number will be the severity of the disease; these generally depend on the sensibility of the organ primarily irritated, and of the system generally. Sometimes the original irritation continues to be predominant; the organ which it affects being the only one to suffer from congestion and disorganization; but occasionally it happens that a secondary irritation becomes the principal; this constitutes *metastasis*. Again, the principal irritation may be transferred to some organ of secretion or exhalation, and is relieved by a discharge from the system; this is what is called a *crisis*. When irritation causes an accumulation of blood in a tissue, so as to produce swelling, redness, and heat, it is called inflammation, this being only an irritation of an intense kind, observing the same laws as irritations in general, except that when unrestrained it proceeds more speedily to disorganization. These appear to be the main features of M. Broussais' doctrine of irritation in general. In describing its further application to particular diseases, he generally uses the terms irritation and inflammation as synonymous, and ascribes to such an affection variously multiplied by sympathy and reaction, and occupying various seats, all febrile diseases, hemorrhages, profluvia, morbid growths, most of the nervous diseases, dropsies, and even occasionally scurvy itself. In all febrile diseases and considerable inflammations the heart is sympathetically irritated, whence the quick pulse and hurried circulation; but the main and most important seats of irritation, either primary or sympathetic, are the mucous membrane of the stomach and bowels, and the brain. In all fevers called idiopathic, these irritations are the primary evils: they are equally so in the exanthematous and some other diseases; and there is not an inflammation of an extent

sufficient to quicken the pulse which does not sympathetically produce a decided irritation of these organs. The cerebral irritation is in most instances secondary to that in the stomach and bowels, and it always reacts on and increases the latter.

Without proceeding further in the details of this doctrine, which Coutanceau has well named the doctrine of irritation, we may sum it up by saying that there is not a disease to which the human body is liable which is not dependent more or less directly on irritation. Such an excessive generalization, it might be expected, would have been confined to the name only, and although it should give a new aspect to pathology, it could hardly be anticipated that a corresponding innovation would have been extended to therapeutics. But the case is far otherwise. Broussais, in ascribing all diseases to irritation, and in viewing in that irritation nothing but a grade of inflammation, recognizes truly curative means only in antiphlogistics, and denounces all other descriptions of remedy as irrational and hazardous. Nor is he less exclusive in his catalogue of antiphlogistic remedies: purgatives and emetics he prohibits as dangerous *irritants* of the gastro-enteric mucous membrane, that soul and focus of all sympathies: diuretics *irritate* the kidneys; expectorants the bronchial membrane; diaphoretics the skin; and instead of counteracting the original disease, they may reflect on it a new and aggravating irritation: the same objection applies in most instances to blisters and epispastics in general. In short, the whole class of antiphlogistic measures is, with trifling qualification, reduced to bloodletting, abstinence, and dilution.

Whatever may have been the triumphant proofs of success appealed to by the sanguine advocates of this doctrine, we refer to the united experience of the enlightened practitioners of this country, we refer to the records of these pages, for abundant evidence that its absolute practical application would be dangerous and unnatural, and that to deprive medicine of the agents that it so sweepingly proscribes, would be to curtail the art of its most salutary aids. Nothing can more strikingly expose the danger of excessive generalization than a familiar and unbiassed study of nature in all the varieties of her powers; and in our opinion the philosopher who would ascribe all natural phenomena solely to gravitation or some such general power, would not be more partial and incomprehensive in his views than the physician who attempts to restrict the still more complicated and diversified derangement of the animal body to an acknowledged but ill defined principle, and to still further limit the practice of his art by a partial view of that principle itself.

Great credit is due to M. Broussais for having fully established the fact, hitherto but little noticed, that local inflammations, particularly in the stomach and bowels, are present in most febrile diseases; that such inflammations are capable of producing great disorder and even inflammation in remote organs, by sympathy through the medium of the nerves;

and that similar affections frequently complicate themselves with and aggravate many chronic diseases. The most salutary results have been obtained from the application of this knowledge to practice, in the judicious use of adequate antiphlogistic measures wherever these inflammations subsisted; and a more qualified and cautious prescription of purgatives and other medicines in similar cases is another good flowing from the same source. But to make the word *irritation* the representative of the origin of almost every disease; to exclude from pathology all views of general morbid states, whether of plethora or inanition, excitement or depression; to refuse to acknowledge in local diseases any diversity of *mode* of action, referring all morbid phenomena and products only to excess or diminution; to exclude from therapeutics the whole class of alternatives, and to exaggerate in numerous kinds of evacuates their stimulant (often unproved) above their evacuant or antiphlogistic effects; to disregard the operation of narcotics, antispasmodics, and other medicines which exert a direct influence on the nervous system, and through it often favourably affect the vessels;—this is to deny ourselves the advantages of daily experience and unbiassed observation, and to render us the slaves of a system instead of the followers of nature.

If M. Broussais were a little more impartial and considerate towards his own principles, and would take more into view that state of the *nervous system* which he acknowledges to be primary in the state of irritation, and which, as existing alone, may properly be viewed as an object of distinct and specific treatment; if he would admit that a certain state of the vascular system is required before the irritation can produce inflammation, and that, therefore, antiphlogistics are indicated only when this state is present; and if he would take into consideration the secretent and exhalent power as well as the inflammability of the vascular system, and recognize the salutary operation of certain alternative, evacuant, and astringent medicines; then his physiological system would stand on a broad and comprehensive basis, and its application to practice would be consistent both with principle and with the general experience of the most successful practitioners. But in its present state we cannot but view this doctrine as partial and exclusive; and we would decline his use of the word *irritation* as vague in pathology, and fallacious in therapeutics.

The sense in which Mr. Travers uses the term is considerably different, but as he does not attempt to give a definition of it, it is difficult to render in a few words an explanation of his views. He seems to apply the name irritation to any disorder of sensation or function, whether of the nature of depression or excitement, that is not attributable to inflammation or to injury of the mere mechanism of parts. It is chiefly through the nervous system that the phenomena of irritation manifest themselves; and this constitutes the character which most distinguishes irritation from inflamma-

tion: but the relation of these two states of disorder must be as intimate as the connection between the nervous and the vascular systems is close and reciprocal. But it will, perhaps, more nearly represent Mr. Travers' view of irritation to say that it is a morbid modification of the irritability of a part or system. Here we are naturally led to inquire what *irritability* is, and what is its healthy proportion and mode of action. Of irritability it can only be said that it comprises the vital properties of a part or tissue, and is shared in various proportions and forms, by the different organs and textures of the body. If there is any rule observed in the distribution of this natural irritability, it is not in the ratio of sensibility, vascularity, or muscularity, but rather according to the importance of the organ in the functions of life. It is much more largely possessed by some individuals than others; and various circumstances, external and internal, are capable of producing a great variety in its proportion in the same individual. An excess or deficiency of natural stimuli, or the operation of noxious agents, will convert healthy into morbid irritability; and again, if the share of irritability possessed by an organ be morbid, natural stimuli will produce irritation. Thus an irritable stomach may be nauseated and disordered by many ordinary articles of diet; an irritable bladder is continually parting with its contents before the stimulus of distention can be supposed to act: an irritable heart becomes tremulous and palpitating whensoever its action is excited; an irritable skin breaks out in a rash from many slight causes of excitement both of diet and temperature. The description which Mr. Hunter gave of irritability in a morbid sense, "over-action to the strength of the parts," and an irritable habit defined as "an increased disposition to act without the power to act with," accord with Mr. Travers' views of the subject, which are further exhibited in the following passage. "Extreme susceptibility and consequent over-activity are invariably coupled with and most probably dependent on weak and insufficient powers of constraint and resistance. The same principle which renders a part over-irritable renders it over-active. The balance of the system, adjusted by the state of even health, is disturbed by the preponderance or deficiency of either of its active functions, as by the imperfection and disease of either of its organs. A weak organ or constitution is one easily put out of order, because it is continually excited to greater activity than it has power to support,—greater, therefore, than is consistent with the harmony of the system. But action may be morbidly excessive or deficient, independently of organization; and this irregularity, although occasional at its commencement, may become habitual. A too irritable, nervous, or vascular function is, therefore, as marked a constitutional peculiarity as irritable lungs or skin. In a physical as in a moral sense, every individual has a weak part, and this observation would as often apply to the function as to the organ. Circulation, or respiration, or nutrition,

in one or other of their many intricate processes, is below par in tone. The absorbent capillary function is below par in scrofulous habits, the arterial in the leucophlegmatic, the venous in those disposed to local congestions; the exhalent in the dropsical; and the pulmonary, gastric, hepatic, and renal, are respectively the failing functions in persons who eventually become the subjects of asthma, gout, jaundice, and stone."*

This quotation, although referring only to susceptibility of irritation, will be sufficient to show the extensive view in which Mr. Travers applies the term under consideration. Irritation in this sense cannot be defined otherwise than as a disorder arising from a want of balance of functions. But as no disorder can exist without more or less of a loss of balance of function, it is obvious that there is nothing in this definition which can distinguish irritation from disease in general. It is, in fact, more according to their causes than by any common character in their symptoms that Mr. Travers groups the cases of disease as instances of irritation, and this is perhaps (especially as far as it relates to surgery) the most practical method of arrangement.

Irritation may be either local or general; that is, one or more organs or parts may be its seat, without the rest of the body partaking of the disorder, in which case it is local; but when the principal functions become affected, the irritation may be called general or constitutional. Local irritation may sometimes become extended to the system, and thus become constitutional; this occurs in cases of severe external injury or disorganization, such as extensive burns, compound fractures, &c. Mr. Travers makes a further division of cases of constitutional irritation into two kinds, direct and reflected. Direct irritation is that wholly and immediately derived from a local source of irritation, the constitution having no share in its production, and is, therefore, proportionate to the local cause. Reflected irritation, on the other hand, originates in a peculiar morbid state of the constitution, is purely idiopathic, and being oftener the cause than the effect of local disordered action, is seldom influenced by local treatment. The symptoms characterizing direct constitutional irritation, are, in the nervous system, rigor, delirium, convulsion, coma; in the vascular, the fever of phlegmonous, suppurative, ulcerative, and gangrenous inflammations. Those which belong to reflected constitutional irritation are, in the nervous system, epilepsy, tetanus in all its modifications, and other anomalous forms of spasm, mania, &c.; in the vascular system, the fever accompanying erysipelas, scrofulous and carcinomatous inflammation, carbuncle, &c.

The division which Mr. Travers has thus made appears to be abstractedly just and natural, and in extreme cases it is sufficiently easy to distinguish between the local and the constitutional origin of disease. But the more numerous cases of a mixed description, where

* On Constitutional Irritation, p. 15.

sympathies and re-actions are multiplied and complicated, and where local disease and a disordered constitution affect each other with equal or balancing forces, will seldom bear an exclusive reference to either of these divisions, and it would be unsafe to found practice generally upon them. They are unquestionably more applicable to surgery than to medicine; and it may be said that a principal part of the *medicine of surgery* consists in a due apportioning of the treatment between the local and the constitutional disease. The enumeration of symptoms, which we have quoted above from Mr. Travers' work, would give to the word irritation nearly as extensive a sense as that in which it is accepted by M. Broussais, since inflammatory and all kinds of symptomatic fevers are included under it, and, physiologically speaking, they are so with great justice; but in a practical point of view, seeing that these affections, whatever share irritation may have in them, have their distinct names and their peculiar and varied forms of treatment, it would seem to us more desirable to limit the term irritation to those affections which partake of the character of excitement or increased vascular action, without the precise characters of fever and inflammation. Irritation undoubtedly attends all inflammations and fevers, but then its phenomena merge in those of the phlogosis or pyrexia, which in a specific and peculiar manner modify the course and determine the issue of the malady. Constitutional irritation is a state so distinct from inflammation, that it has been remarked, and very justly, that in its characteristic form it is incompatible with it; the former ceasing to exist when the latter is established. It must, however, be admitted, that these two states pass into one another by gradations that it is often impossible to distinguish. Irritation may be considered to be the introduction or preliminary state to inflammation: it is the mobile part of it, and being transferred from one locality to another, draws the phenomena of inflammation after it. But it may exist independently of inflammation: certain additional circumstances are required for the production of the latter; if these are wanting, and the source of irritation still exists, a variety of phenomena ensue, expressive of excitement and disorder of function. What these additional circumstances are, we cannot absolutely specify; but a certain degree of plethora and power in the vascular system are elements which seem to be required before irritation can produce a true inflammation. It is such a plethora and susceptibility of the vascular system which constitutes the phlogistic or inflammatory diathesis; and where this is strong, irritations even of a mild nature may readily become extended to the vessels and pass into inflammation. Where, on the other hand, the vascular system is ill filled and of low power, any irritating cause failing to excite it to inflammation develops its effects in various other modes, such as disorder of sensation, secretion, and other functions, the nervous system being apparently the medium through which the irritating influence

acts. Between the states of pure irritation and perfect inflammation there are, however, numerous intermediate gradations, in which the phenomena of irritation beyond what usually accompany inflammation manifest themselves, and prove, even in disorder, an unequal balance in the systems. So general is this fact that there is not a malady of any kind in which more or fewer of the signs of irritation are not *occasionally* apparent, and the history of irritation in this sense would extend to varieties of the whole catalogue of diseases. Such a view would be far too extensive for the due limits of this article. We shall, therefore, merely give a sketch of the pathology of irritation in general, and conclude by a notice of the most remarkable examples of the different kinds of irritation.

Of irritation in general.—The introductory view which M. Broussais gives of irritation is far less objectionable than the indiscriminate and unqualified application to which he afterwards extends it; for truly, the reference of disease to changes in the physiological properties of tissues, if unbiassed and comprehensive, is, as far as diseases of the solids are concerned, a fair and natural basis of pathology. But to specify contractility and sensibility as the only properties of tissue appears to us to be too hypothetical to be admitted as the ground-work of a doctrine; and as there is no necessity for analyzing functions, it is better to treat them simply as they present themselves. Neither are we inclined to adopt the dogma of M. Broussais, which is only a modification of that of Brown, that there is always an equal quantum of excitability in the system, and that an increase in one part necessarily produces a diminution in the other, and, therefore, that there is no such a state as general asthenia or as general excitement.

The functions of animal structure are relative; certain circumstances excite or increase, and others diminish or depress them: exciting agents are called stimuli or irritants; those which depress are called sedative. The relation of an irritant to a function is *irritation*; but the signification of the word here is twofold, for it implies, 1, the agency or act of irritating; 2, the effect or the excited state of the function. It is not unimportant to observe this distinction, and as the construction of our language does not admit of it in the word itself, we shall endeavour to restrict *irritation* to the latter meaning, and describe the other as the *irritating influence* or *act*. Without attempting to explain them, it will be convenient to represent the living properties in general by the word irritability, which merely denotes their relation in the abstract to irritants. There is a certain share of irritability natural to the healthy state of every part, and the moderate operation of natural irritants upon this constantly induces that degree of irritation which constitutes healthy function. Irritation in a morbid state implies excess, which, when great, sufficiently declares itself by the disorder or loss of balance that ensues; but in smaller degrees morbid irritation is as hardly discerni-

ble from healthy as slight disease is from health.

Irritation may arise from an excess of irritability in a part independent of external circumstances, so that the ordinary or habitual stimuli become irritants; or it may proceed from an additional irritating influence from without. Thus vomiting is a symptom of irritation of the stomach; and it may arise from excessive irritability of that organ, as in gastritis, and in the sympathetic irritations of the stomach from concussion of the brain, diseases of the urinary organs, pregnancy, &c.; it may on the other hand proceed from the additional irritating influence of an emetic or of indigestible food. So, likewise, irritation of the mucous membrane of the lower intestines may manifest itself by diarrhoea; and this irritation may proceed from the over-irritating quality of the contents of the intestines, as in bilious diarrhoea, and the operation of a drastic purgative, or from the excessive irritability of their membrane, as in dysentery, lentergy, &c. Again, the urinary bladder shews signs of irritation when subjected to the unusual stimulus of gravel or stone; and the same phenomena are presented when, either from disease in its coats or by sympathy with some adjacent parts, as in stricture of the urethra and rectum, scirrhus uteri, ascariides, &c., the irritability of the bladder is inordinately increased, and it is continually parting with its natural contents. This division of the modes of irritation is useful, inasmuch as it points out a distinction which is sometimes of the greatest importance in practice, but it is one that cannot always be made; for the two modes frequently unite, and an excessive irritating influence very commonly induces an unnatural irritability of the part to which it is applied. Thus, after an emetic or other irritating substance has been rejected from the stomach, the organ continues for a while morbidly irritable, and refuses to retain the blandest liquids; and the bladder often remains irritable after all the gravel has passed away. Again, when the irritability of a part is low, what is commonly an irritant may fail to produce irritation. Thus an emetic sometimes fails to excite vomiting; crude and indigestible food may pass through the stomach, and fæces may accumulate in the intestines without injury; worms may inhabit the viscera, and gravel lie in the bladder, without any remarkable signs of irritation in the respective organs. The same remarkable difference in the susceptibility of irritation is observable in the same individual under different circumstances, and even simultaneously in different parts of the same system. To say that this susceptibility of irritation depends on the degree of sensibility is only to adopt another mode of expression without making the matter more plain. It is generally under the influence of a new or additional irritation that a part becomes awakened to the presence of irritating matters of which it was before insensible. Thus an inefficient purgative frequently develops the irritating influence of fæces long accumulated in the cells of the

colon; an excess of diet renders the urinary bladder sensible of the pressure of a calculus hitherto latent; a fit of indigestion occasions irritation of a tumour or other organic disease in the brain to produce a fit of epilepsy. But it is through the medium of the nervous sympathies, which produce what is called constitutional disturbance, that local sources of irritation are most frequently excited. Any thing that disturbs the balance of the functions in general is sure to be felt in the weak or disordered part; and a cause of irritation, which may be long latent during the quiet and equal action of functions, is thus called into activity by any general exciting influence, and, if extensive, often reacts with great energy on the constitutional disease. Again, a local irritation frequently extends itself to the various functions of the system, generally affecting them irregularly and singling out a weak organ, which becomes a new seat of irritation, whilst the original evil receives back with interest, by the same channels of sympathy, the disturbing influence that it had engendered. This interesting subject has been ably treated by Abernethy, Travers, and other eminent writers on medical surgery; and its importance is generally admitted in modern practice. We here allude only to its principle, which is not dissimilar to that of the cases already noticed.

We have hitherto represented irritation as the result of a stimulus or exciting influence, whether the undue relation reside in the irritability of the part, or in the external influence applied to it. The nature of this relation is necessarily obscure, as it is involved in the mystery of the properties of organized matter; and we must therefore at present rest contented with observing the fact. But there is another source of irritation which it is important to notice, equally proceeding from the operation of a prevailing law of organized structure. There is in the living powers a kind of resiliency, or disposition to reaction, which manifests itself after the application of any influence that tends to depress or destroy them; this property often converts sedatives into indirect irritants. Thus cold is in itself a sedative; but the re-action, which succeeds to its application, renders it a fertile source of inflammation and irritation. The worst mechanical injuries and severe burns and scalds are likewise sedatives in their immediate effect; and when extensive, this is sufficiently apparent in the syncope, suspension of sensation and function, and even death, which they occasionally produce. There are many instances on record of death supervening on severe accidents, such as the crushing or tearing of limbs, compound fractures, violent blows on the head, epigastrium, or thorax, &c. in which it could not be ascribed to loss of blood, or mechanical injury of any of the vital organs. The death of patients under severe surgical operations without hemorrhage may be attributed to the same cause, assisted often by the powerfully sedative influence of fear and pain. A remarkable and instructive illustration of the

influence of mechanical injury may be drawn from the experiments of Legallois, Wilson Philip, Majendie, and others, in which it appeared that violent and extensive injury done to the brain and spinal marrow of animals caused an immediate cessation of the action of the heart, whilst the removal of the whole or any part of these organs in a state of integrity produced no such effect. Bruising or roughly lacerating the brain, or forcing a coarse instrument into the spinal marrow, seemed in these cases to exert a positively noxious and sedative influence on the heart. A more intelligible cause of prostration is loss of blood; but this, although it certainly is so when syncope and death are its immediate consequence, is not, as we shall presently see, so complete and general a sedative as some of the other influences which we have named. Other evacuations and privation from food are essentially of the same nature, but the gradual manner of their operation gives occasion to various signs of re-action, which disguise their direct effect.

The immediate operation of all these causes (and they constitute a most numerous class, for contagious effluvia, malaria, septic and other pestiferous influences may be added to the list,) is unquestionably sedative, or that of prostration; and if the powers of the system should be insufficient to resist or rally from it, they succumb under it. This is the very reverse of irritation; yet, strange to say, it has been commonly confounded with it; and it is when applied in this way to such opposite affections, that the word has lapsed into an indefinite acceptation. If the powers of the system are not subdued by the prostrating or sedative influence, there will then be re-action, in which they usually tend to pass the limit of moderation and regularity, and irritation and excitement ensue in the functions, various in kind and degree, according to the share of power which they severally retain. This appears to be a general rule in the animal economy, and we are not required to go further for an explanation of the reaction which forms a prominent part in many diseases. This reaction may be partial and injurious, as where it displays itself in convulsions, vomiting, hiccup, palpitation, cramps, &c. These symptoms have been called indications of prostration, and so perhaps they may be admitted to be with regard to the system at large, but certainly not in respect of the organs which they affect; in these they are unequivocal signs of excitement or increased action. They are proofs of impotent and misdirected reaction, and if not seconded by a re-animation of the organs more immediately concerned in the support of life, they exhaust the excitability of the system, and accelerate the extinction of life.

Another remarkable symptom of reaction is rigor. The addition of this sign to those already mentioned implies a greater degree of power in the system; and in many instances it precedes the development of the highest degree of reaction. Thus it is the first sign of fever,

in which it is followed by a series of irritative movements of an intense and general kind. On the other hand it is the symptom of healthy and moderate reaction from syncope; and it frequently succeeds to the sedative impressions of cold without any violent irritation ensuing. It may be represented to be a slight convulsive motion, the object of which is to give an impulse to the circulation of the surface. When reaction becomes more general and perfect, it verges on fever, which may be inflammatory or nervous, according to the prevailing strength of the sanguiferous or the nervous system. But it is to the degrees short of fever and inflammation that we here restrict the application of the term irritation, and in these we find many, but not all, of the functional disorders which attend fever. There is a marked perversion of the functions of circulation, respiration, and digestion. In the former we see a quickened and irregular pulse, with deficiency of force and firmness in the heart's action; whilst alternations of pallidity and flushings betoken an equally irregular tonicity of the capillary vessels. The breathing is anhelatory and distressed; and this sometimes depends on the irregular state of the circulation, and sometimes on the irritation affecting with spasm the bronchial muscles. The powers of digestion may be often said to be almost annulled; a total inappetency for food marks their defect; and we need only allude to the loaded state of the tongue and to the vitiated excrements, as a presumptive proof of the existence of an adequate cause in the depraved state of the visceral secretions. The sensorial functions are likewise variously affected by any irritation extensively present in the body. The sensations and perceptions are commonly exalted and acute, while the other mental powers are below par; hence an irritability of temper and depression of spirits are generally observed; and the loss of balance sometimes amounts to delirium, which is usually of the morose or angry kind.

In the various symptoms that are thus presented in diseases of irritation, we should err were we to expect to trace constantly the features of excitement. It is the loss of balance which is most apparent; and although there must be some undue and misdirected excitement or irritation in some part of the system, the remaining functions will generally (but not necessarily) suffer from prostration and weakness. The more general states of fever and inflammation, through the vascular system which they essentially affect, in their marked and acute forms, entail irritation and excitement of a more equally diffused kind; but irritation, as we consider it, may be confined to a function or organ, while the remainder of the system is suffering from decided asthenia. Thus the stomach and bowels may exhibit irritation in profuse secretions and inordinate movements, whilst other secretory and motory organs are in a state of complete inactivity and prostration. The mamma and the testis sometimes present a form of irritation in an excessive sensibility or constant pain, without any

apparent excitement or weakness in their vascular structure. It is in fact a degree of relative, not absolute weakness, that characterizes irritation through all its range of degrees. The excitement takes effect partially only, and the parts unaffected do not contribute to carry the orgasm through a series of processes by which it is at length exhausted, as in the case of inflammation; but if the cause continues, the irritation may persist for an indefinite time, occasioning more or less mischief and disturbance, according to the importance, in the system, of the balance which it destroys. In the greater number of instances of irritation, the vital powers are enfeebled; and this constitutional weakness is the reason why the excitement does not become general and pass to the state of fever or inflammation; but absolute debility is not essential to the existence of irritation; since the most perfect inflammations and sthenic fevers commence with simple irritation, and this is a stage in all cases of reaction. The persistence or protraction of irritation certainly implies relative, and in most instances, general weakness; for the existence of power would lead either to general reaction and restoration of balance, or to the more powerful process of pyrexia and inflammation. The operation of the morbid virus received into the system through wounds in dissection strikingly illustrates two modes of irritation. Its local effect is that of direct irritation, while its action on the system is that of powerful prostration, against which the feeble and irregular reaction of the vital forces develops another kind of irritation. If in such a case inflammation begins in a part, it seldom exhibits the vigorous and decided character of healthy inflammation; but occupying the capillaries principally, and unseconded by any energetic action of the other parts of the vascular system, it takes on an erythematous form, while the effusions are serous or sanious, destitute of coagulable lymph, the plastic effect of which tends to limit and restrain phlegmonous inflammation. The variety of signs which this complication of disorder may present is very considerable; but they principally depend on these two causes—the noxious or sedative influence of the poison, and the irritation resulting from an imperfect and irregular reaction of the vital powers against it. For a full and interesting detail of examples of this kind we must refer our readers to the work of Mr. Travers, before quoted.

We may, in conclusion, sum up the kinds of irritation under three heads:—

1. Those caused by *direct* irritants or stimuli, whether acting immediately on the part, or mediately through the nerves.

2. Those caused by a preternatural irritability, which, independently of any new exciting influence, renders the relation of ordinary circumstances a source of irritation.

3. Those caused by *indirect* irritants, or those influences which, although in themselves prostrating or sedative, become irritant through the reaction of the vital powers against them.

This division must be admitted to be in

some measure artificial, inasmuch as few examples of irritation occur in which one only of these kinds of causes prevails. They, particularly the first and the second, frequently become engrafted one on another, and occasionally all coexist; but still the greater number of cases are sufficiently stamped by the prevalence of one or other of these kinds of irritation, to render the distinction available in practice.

1. *Diseases of direct irritation.*—Of this kind is the disorder resulting from all sorts of slight mechanical injury, whether by contusion, super-extension, puncture, incision, or laceration; from extraneous substances, tumours, effusions, and accidental productions; chemical irritants, too long retained or vitiated excretions; dentition, crudities, and worms in the alimentary canal, calculus in the urinary or biliary passages, and many others. Irritation in all these cases is undoubtedly the result of a reaction of the vital powers, the object of which is salutary, being the removal of an irritating matter, or the reparation of an injured part. Whether there be a state prior to reaction which can bear the name of prostration in these cases, as well as in those of the third class, is a matter of merely speculative and not practical interest, since we can detect in their history no other than a direct mode of irritation. The reparation of an injured part depends mainly on the vessels obeying the impulse of irritation; and unless there be a peculiar defect of power in them, the disorder passes into the more healthy state of inflammation. Where this defect subsists, there may be either the imperfect inflammatory action which we see in erythema and erysipelas, or no inflammation at all, and then pain and disordered function or secretion are the signs which attend irritation. It is for the same reason that injuries of tendons, ligaments, fasciæ, and other fibrous membranes, commonly exhibit more of irritation than of inflammation; they are not liberally supplied with vessels, and the irritation, instead of speedily terminating in the reparatory or suppurative process, lingers longer in the part, with pain, serous effusion, &c. sometimes exciting, sympathetically, severe constitutional derangement, and even tetanus. In the irritation resulting from the application of mechanical or chemical irritants, the salutary object of the reaction is more apparent. Thus, if a grain of sand or salt fall on the conjunctiva, the pain and irritation excites a copious secretion of tears, the tendency of which is to remove the offending matter. Mucous membranes, when irritated, throw out viscid mucus to protect themselves. When a thorn or a needle penetrates the skin, an irritation is produced, which tends to inflammation; this by effusion limits the irritation to the immediate vicinity, and by suppuration removes the irritating matters. But, on the other hand, irritation may fail of its salutary end in all these instances. The grain of sand may remain lodged; the mucous effusion be inefficient as a shield; and the vascular power may be insufficient to effect the process of the expulsion of the thorn or needle;

and then the irritation becomes a disease of more permanent character. So worms in the intestinal canal will irritate the membrane of the bowels in every variety of way but a salutary one. Thus they may affect the nerves, occasioning by sympathy grinding of the teeth, convulsions, disordered appetite, various pains, palpitation, &c. The vascular system may likewise be excited, and mucus poured out in great quantity, the peristaltic motion accelerated, without dislodging the offending bodies; whence diarrhœa, with tormina, depraved excretions, thirst, atrophy, and other constitutional disorders, may ensue. The same description will apply to scybalous fæces lodged in the cells of the colon. Indigestible food and excess of acid or acrid secretions in the stomach irritate it in a variety of ways: if the sympathies of the muscular apparatus related to it are quick and susceptible, vomiting is excited, and the end of the irritation accomplished. But if these are not sufficiently roused, the irritation will cause other sympathies and uncomfortable feelings, both bodily and mental; whence arise gastrodynia, pain in the chest, incubus, palpitation, asthma, headach, vertigo, hypochondriasis, &c. The signs of irritation may proceed from such a variety of organs that it appears to be in a manner reflected from one to another. Thus irritation in the bowels is transmitted to the brain and spinal marrow, and from thence develops its effects on the voluntary muscles, producing spasm, convulsions, or chorea. If the original irritation persist long in this direction, it may become fixed on the nervous system, and there continue long after the irritating influence has been removed from the intestines; the disorder of the nervous system may then be considered to be of the second kind of irritation, that, namely, of increased irritability. Calculus of the urinary organs frequently produces irritation of a still more disturbing and unprofitable kind, which has worn down the feelings and functions of many a frame. Dentition is another fertile source of irritation in the bodies of sensitive children. As long as this is restricted to the production of a copious flow of saliva or a moderate diarrhœa, it can scarcely be said to be prejudicial; but it not unfrequently amounts to generally disordered secretion, wasting diarrhœa, and atrophy, convulsions, and paralysis; none of which effects tend in any intelligible way to promote the progress of the tooth through the gum. Tumours in the brain or spinal marrow may excite epileptic convulsions, chorea, paralysis agitans, &c. Accidental productions, as tubercles, produce various signs of irritation, both local and sympathetic. Thus, in the lungs they occasion cough, in the bowels diarrhœa, &c., whilst their presence almost always irritates the heart and quickens the pulse. Foreign bodies or splinters of bone in the substance of living structure frequently occasion severe irritation, with little or no decided inflammation. It may declare itself by pain and spasm in the part, and in the system by disorder of any of the functions, quickened pulse, hurried breathing, impaired digestion,

delirium, convulsions, tetanus, &c. Pus confined within the proper sheath of a tendon, under a fascia, or within any dense and unyielding tissue, may produce similar phenomena.

Such are examples of direct irritation, and many others might be adduced; as the history of numerous diseases, medical and surgical, abounds in instances of the same kind; but we do not profess to enter into details, and enough has been said to illustrate the principle. Nor shall we do more than allude to another important and extensive cause of irritation, which we cannot hesitate to call direct,—inflammation. It is a cause not only sympathetically, or through the intervention of the nerves, but likewise by mere contiguity. Thus inflammation of the pulmonary pleura excites irritation and consequent inflammation in the corresponding part of the costal pleura; and the same thing gives origin to the adhesions observed between the heart and pericardium, and the peritoneum in its various points of contact. The physical nature of this mode of the propagation of inflammation is involved in much obscurity; and although there are not sufficient grounds to identify it with electric or galvanic action, it is obviously something beyond vascular or nervous communication. But through sympathy an organ or part affected with inflammation produces irritation in various other organs; this is fully exemplified in what is called symptomatic fever, which can be referred to no other principle. It is, moreover, especially remarkable in the sympathetic relations which subsist between particular organs, as the mucous membrane of the stomach and bowels, and the brain. And here, while we would acknowledge the truth and importance of the views of M. Broussais on these points, we would insist still on the propriety of distinguishing between inflammation and irritation. The secondary or sympathetic irritations may truly pass into inflammation; but they more generally fall short of it, and therefore require a different treatment; and it is a point important to be observed, that instead of being in proportion to the intensity of the primary inflammation, they are often most prevalent when this is very slight. Thus the cerebral and general irritation accompanying well-marked gastritis is considerably less than that which gastric derangement, or what the French call "*embarras gastrique*," will produce. It would, perhaps, more nearly represent the reality if we say that the sympathetic disorder is in proportion rather to the irritation of the organ primarily affected than to the intensity of the inflammation. This predominance of irritation over inflammation, although occasionally occurring in the robust, is a character more remarkable in individuals in whom the nervous system has the ascendancy, whether by natural constitution, or in consequence of the depression of the vascular power by evacuations or inanition. It is thus that in delicate females visceral inflammations are often accompanied by irritation and disorder quite disproportionate to their intensity or extent.

Certain mental emotions are frequent causes of bodily irritation, and they act in a variety of ways. Anger, joy, and surprise, (which act as general stimulants on a healthy body, and as if they tend to produce disease at all, it is congestion or inflammation,) when the bodily powers are in an enfeebled state, become direct irritants, and develop that partial and irregular excitement among the functions and sensations which we understand by the word irritation. They exert their stimulant relation almost exclusively on the nervous system, which in this condition of the body has already a disproportionate ascendancy, and they may thus greatly increase that loss of balance which is so much opposed to the state of health. Thus we see the necessity of excluding all such influences from those whose functions are in that state of weakness or depression which continually verges on derangement; such are convalescents from fever and other severe diseases. Grief, fear, and anxiety are indirect irritants, and must therefore be referred to the third head.

2. *Irritation from excessive irritability.*—We have already adduced examples of this kind in the case of the stomach after the evacuation of an emetic during pregnancy, or suppression of urine, and under the influence of concussion of the brain, and other injuries or shocks to the system. The intestines, when once excited by an irritant, sometimes present a continuance of irritation apparently from the same cause; and the irritability of the urinary bladder is known to be morbidly exalted in diseases of the adjoining parts. Inflammation is, however, the most common cause of excessive irritability; and it is in some measure a question whether the above examples may not be referred to a state more or less akin to it. But we see parts sometimes remain permanently irritable without any obvious increase of vascularity; and as there is reason to suppose that sensibility is not always in proportion to the number and size of the vessels, it would not seem just to attribute the excessive irritability of an organ always to inflammation or even to congestion. Mr. Travers considers that the irritable joint, breast, testicle, and prostate gland, give no evidence of inflammation. He records instances of irritable breast and knee-joint, attributed originally to needles having entered the parts, which continued painful many months after the extraction of the needles, in the total absence of inflammation. The facial nerves in those affected with tic douloureux present examples of excessive irritability; a draught of cold air or the heat of a fire is enough to irritate them and the adjoining muscles into pain and spasm. The bronchial muscles are inordinately irritable in those subject to nervous asthma; and trifling causes, such as the effluvia of a stable, excite them to spasm. Other idiosyncrasies might be quoted in proof of excessive irritability as a cause of irritation. After an irritation has been transmitted for a considerable length of time from one organ to another, the latter sometimes adopts the habit, and continues to show signs of the same disorder after the original

irritating cause has been removed. This is instanced in chorea, arising from feculent accumulations or disordered secretions in the intestinal canal. When these have been removed or restored to a healthy condition, the chorea sometimes continues, and can only be removed by remedies directed to those parts of the nervous system in which the irritation has become fixed.

The uterus, in the irregular performance of its periodic function, is frequently the seat and focus of irritation. The nervous excitement, or *innervation* as Andral terms it, by which a flow of blood is called to this organ at particular times, may fail of its purpose, and instead of being relieved by the establishment of the catamenial discharge, displays its effects in the various forms of what is called hysteria. In this there may or there may not be local plethora; if there be, the fault of relief must be in the secernent vessels of the uterus; but if there be not, the defect is probably in the sanguiferous system, so that they do not answer to the call. Each of these cases has its separate class of symptoms originating in irritation; but as hysteria and other derangements of the uterine function are fully considered under their respective heads, we do no more than name them. Many other examples might be adduced to illustrate this mode of irritation; particularly in that numerous class in which a congestion or increased vascularity is the cause of excessive irritability; but it is unnecessary to go further. It is by producing a state of this kind, that direct irritants may become causes of this second order of irritations. We may remark that many of the following class of irritations might perhaps be referred to the same head.

3. *Indirect irritation, or the irritation of reaction.*—In developing the principle of this mode of irritation, we have already cited many instances of its occurrence: these may be greatly multiplied, for they are as numerous as the sedative or prostrating agencies to which the animal frame is liable; but it will be sufficient if we notice generally the forms which they most commonly present. There is probably a successive gradation of conditions from the slightest sign of partial reaction from the state of prostration, such as vomiting, rigor, and convulsion, up to a decided and violent reaction, bordering on inflammation and fever. All these we would designate as degrees of irritation dependent on the same physiological principle, and deriving the variety of their aspect from the number and force of the functions which take part in the reaction. We sometimes see it confined to a single organ; thus the stomach shews it by vomiting, the diaphragm by hiccup, the brain by delirium; whilst all other organs may remain in the state of prostration. Of this description is the effect of violent and extensive injuries or burns, and severe operations, in which the powers are almost overwhelmed by prostration, and the partial effort at reaction, instead of counteracting it, contributes to render it complete and fatal. The pulse here is quick and threadlike, the respira-

tion short and suspirious, frequently with a general rhonchus throughout the chest; if there be no delirium, the intellectual and sensitive faculties are in a state of hebetude approaching to stupor; the pupils are dilated, and the eyelids half closed; the countenance pallid or livid; the surface and extremities cold; the secretions, if not suppressed, are unnatural; and the sphincters often fail in their office. All these are signs of direct prostration, and among them the irritation of reaction may declare itself in a solitary symptom, and in none more commonly than in vomiting, which is often indomitable to the last, and greatly hastens the fatal event. It seems to proceed from extreme irritability of the stomach, which rejects the blandest liquids. A low delirium, with various hallucinations of the perceptions, may equally accompany this state; it is a sign of the irritation of reaction in the brain, and is prejudicial both in being misplaced reaction, and by leading to bodily efforts which add to exhaustion, and not uncommonly prove instantaneously fatal. Convulsions arise in the same way, and produce similar effects. Such is exhaustion with the lowest signs of reaction. In other cases irritation takes a larger share in the diseased state consequent on the injuries under consideration. Thus, after rigors, the pulse may become sharp and bounding, with throbbing in the head; the eyes glassy, with contracted pupils; the delirium fierce, or there is great restlessness and morbid sensibility: spasms may occur in various parts of the body; there may be pain in all degrees and positions; the heat may be partially increased, although the extremities are generally cold. Here, although beginning in prostration, the chief features of the disease are those of misdirected and excessive reaction. They border very closely on fever and inflammation; and it would be rash to say that they are always distinct from these states: but although the delirium and exalted sensibility are sometimes so marked as to give suspicion of the existence of phrenitis, examination of the brain after death discovers no sign of increased vascular action further than some turgescence of the vessels, which is totally disproportionate to the intensity of the symptoms. Other organs, the lungs, the heart, the stomach and intestines, but particularly the serous membranes, are occasionally the seat of this kind of irritation, which puts on the semblance of inflammation; but less commonly in reaction after local injuries or operations, than after prostrating causes which have a more diffused seat in the system, such as cold, loss of blood, and inanition. The general tendency of all these irritations is to exhaust, and unless controlled and counteracted, they wear down and destroy the remaining irritability of the system, and death necessarily ensues.

It is the continued impression of a sedative or prostrating influence that renders reaction imperfect, and converts it into an injurious irritation. Thus the powers in general may be unable to rally after the first shock of any severe injury or operation; but this inability is frequently dependent on some additional sedative

influence, bodily or mental. Fear and anxiety are most powerful in this way; and instances are on record in which operations, trifling and favourable in their surgical relation, have led under their influence to a fatal result. Women have died after successful and natural parturition, barely from the effect of a presentiment that they would die. To such instances cited in Mr. Travers' work before mentioned, he adds a case of the death of a lady after a labour protracted unusually by the evolution of a polypus after child-birth; and another of a gentleman who died in twelve hours after the escape of the contents of the stomach by perforation into the peritoneal cavity—ascribing these fatal events to the sudden, extreme, and unremitting pain: but we question whether they may not be as fairly attributed to exhaustion from muscular effort in the first case, and in the latter to the prostration of the heart's power by the severe and extensive injury to the peritoneum, as in other cases of acute peritonitis. Pain, although commonly at first a powerful irritant, when exceedingly severe occasions syncope, and by fatiguing the powers otherwise produces a prostrating effect: in this way it will tend powerfully to subdue the disposition to general reaction. It implies the worst species of mental excitement, which entirely prevents the repose essential to restorative reaction; but as we sometimes see the body bear pain even in its greatest degrees with impunity, and as we know that a certain integrity of the functions is necessary for its continuance, we can scarcely look on it as being ever alone a sufficient cause for fatal prostration. The sedative influence of grief and fear is so decided, that they may not only aid other causes, but by themselves destroy by prostration; and this may, as in other cases, be with or without irritative reaction.

But the most remarkable species of causes of irritative reaction are those which depend on inanition, whether arising from bloodletting or other evacuation, or from imperfect nutrition. We owe to Dr. Marshall Hall the first distinct notice of these morbid affections: his observations have been confirmed by Dr. Abercrombie, Mr. Travers, Dr. Gooch, and other subsequent writers; and he has since given a fuller account of them in his "Researches on the Effects of Loss of Blood," a work recording some new facts of great practical importance.

The immediate morbid effect of loss of blood, if extensive, is the same as that of the other prostrating influences which we have mentioned, syncope, coma, convulsions, and delirium. The two latter, although they appear closely allied to the others, we cannot but view as different in their nature, and as resulting either from a partial effort of reaction, or from a remnant of local power, preponderating unduly over general prostration. They most frequently occur where the excessive loss of blood has been gradual, as by atonic hemorrhage, epistaxis, by bloodlettings often repeated, or through a small orifice and in the recumbent posture. The gradual draining of the system in these ways, or by other excessive

evacuations, such as continued purging, and by starvation, which have the same effect in the feeble, after the lapse of these symptoms frequently gives rise to a train of signs of irritative reaction of more prominent and decided form. There will be palpitation of the heart, with quick and jarring pulse, and throbbing of the carotids, aorta, and other arteries, and the auscultator will perceive a purring or grating sound in these parts. If this irritated state of the circulation continue, it will induce its effects on the sensations and functions; sensibility will be increased, with intolerance of light and sound, pain, throbbing, and noises in the head, an excited state of the mind amounting to delirium, a loaded tongue, and general disorder of the secretory functions.

This condition, which is amply described by Dr. M. Hall in the work before quoted, and in the articles BLOODLETTING and ABSTINENCE in these volumes, is a fair example of irritation in its characteristic form. Here is great excitement and disposition to act, but no power to regulate or support it: here are the nervous phenomena of inflammation without that permanent and powerful state of the vessels which can lead it to any of its usual terminations. The semblance of inflammation which it frequently presents often induces the practitioner to draw more blood; the evil consequences are sometimes immediate, syncope, convulsions, and death; and when there is a temporary amelioration, it is only a prelude to a worse return of irritative reaction. So great is the real weakness in the midst of all the apparent signs of excitement, that the erect posture or any kind of exertion may prove fatal. It may terminate fatally also in a more gradual way, by passing again into the state of sinking or pure prostration; and here likewise it may put on a fallacious aspect in its resemblance to the signs of effusion on the brain. In children particularly, this imitation is so close that Dr. M. Hall has called it the hydrecephaloid disease. In favourable cases irritation terminates in subsidence and a gradual restoration of power, and with it a recovery of balance among the functions. But the irritation may pass into a chronic state, and of this description Dr. Hall considers puerperal mania, amaurosis, deafness, paralysis, &c.

The delirium, mania, and increased sensibility in those suffering from privation of food, recorded in several cases by Dr. Currie, Dr. Latham, Andral, and others, are obviously of the same nature of irritations of reaction; and in the pain of the head and stomach, and irritable state observed in those under the influence of a great and sudden lowering of diet, we see a more familiar illustration of the same kind. Similar symptoms often accompany the wasted and atrophied condition of infants unduly nourished, with whom the maternal milk disagrees, or whose powers of digestion cannot master the food that is given them; and they not unfrequently develop themselves in the asthenia lactantium, and in any form of undue nutrition. For further illustrations, see

the articles ABSTINENCE, CHLOROSIS, and DISEASES OF LACTATION.

Treatment of irritation.—Having described irritation as a general pathological principle rather than as a specific disease, our remarks on the remedial measures calculated to counteract or remove it must be equally in the abstract, and merely illustrated by prominent examples.

The removal of the irritating influence, if possible, is the most obvious indication in the cure of direct irritation; and in the slighter cases this may be a sufficient remedy. Thus, the removal of irritating matter from the stomach by means of an emetic; from the intestinal canal by a purgative; the counteraction of acidity by a dose of alkali; relieving by a stroke of the lancet the tension of the swollen gum in dentition, or of the integuments or a fascia in superficial or deep-seated abscess, may amount to a complete cure of the various forms of irritation, which these causes severally occasion. But it is not always possible thus to reach the root of the evil: moreover, as we have already remarked, when once planted, the disease propagates itself so as in a degree to become independent of its first cause, and thus to belong to the second class of irritations. Hence it often becomes necessary to combine, with the measures directed to remove the irritating influence, others calculated to diminish irritability; and where the original cause is obscure or baffles our efforts, this is the only system of medication that can be pursued. This combination is the more expedient in intestinal irritation, as the remedies suited to remove the offending cause in themselves for a time aggravate the irritation. Thus it is proper in such cases to give before or with the purgative some narcotic, such as hyoscyamus or opium, and further, if necessary, to allay the irritation of its operation by diluents, the warm bath, and other derivants. It is not easy to lay down any rule by which the relative importance of these measures can be decided; but the sedative plan is generally more requisite in proportion to the length of time and the degree in which the constitution has suffered under the irritating influence. Where the irritation is vehement, and disturbs in a serious degree the vital functions, it becomes of more importance immediately to allay this by temporising measures, than to rest solely on those which are more radical, but of slower operation. A child suffering from worms or accumulated feces may die of convulsions under the additional irritation of a purgative before its evacuant effect can be obtained; but if this medicine be preceded by or conjoined with others calculated to soothe, such as hyoscyamus, Dover's powder, or the warm-bath, according to the character of the irritation, its operation will be safe and seasonable. The purgative is, moreover, by the same means, often rendered more effectual for the removal of the irritating matter, since its slower progress enables it to act more generally on the canal, than where an excessive irritability hurries it precipitately

through. So also, during the prevalence of violent spasm, an antispasmodic must often be promptly administered without regard to the duration of its effect. To give ether, laudanum, assafoetida, valerian, &c. in spasm of the glottis or bronchi, or in violent palpitation of the heart, may be, in relation to the cause of the irritation, a temporizing measure; but it is using time to good purpose.

We have enumerated inflammation among the causes of direct irritation, and we again allude to it for the purpose of remarking, that besides the removal of the cause itself, our attention may sometimes be usefully directed to the quieting of those nervous sympathies by which the irritation is communicated to the system at large. This, we apprehend, is the principle of the salutary operation of opium in continued fevers and the less sthenic forms of inflammation; and did we possess a medicine that should be sedative to the nervous system without exciting or disturbing the vascular, it would furnish a still happier and more satisfactory illustration.

There are many cases in which the source of irritation is organic, or beyond the reach of remedies; it is thus with tumours in the brain, spinal marrow, and other parts, accidental productions, cancer, and other forms of diseased structure; here our only resource is in measures which allay morbid irritability. We shall have occasion presently to revert to this subject; but we see no need to dwell longer on means for the removal of irritating influences; they vary with the nature and locality of the influence.

There is another mode of treating direct irritations, which it may be convenient to notice in connexion with direct irritation, although it is more frequently applicable to the indirect kind, namely, by stimulating applications. In enumerating examples of direct irritation we named various mechanical injuries, and remarked that the object of irritation in these cases, the reparation of the injured part, is sometimes defeated, and the disorder prolonged in consequence of the low power in the vascular system, which is inadequate to take on the reparatory state of healthy inflammation. Here, then, an additional stimulus to the vessels, conjoined, if need be, with a sedative to the excited nerves, will often recal the irritation from its prejudicial wanderings through the system into a local and salutary channel. This treatment is obviously applicable only in cases where inflammation is not in itself a hurtful process, such as mechanical injuries and sores of the exterior, and especially burns and scalds. The efficacy of stimulating applications to the latter is now generally admitted, and we would attribute it entirely to this principle in all the moderate examples of these lesions. The extreme heat has so paralyzed or weakened the vessels, that although they may be entire and congested with blood, they require a new and powerful stimulus to bring them to that activity of function which the reparation of the injury requires. When a part has been disorganized, and is insusceptible of revivification, and the

adjoining vessels are weak and inactive, stimulant applications are still more obviously indicated to excite that inflammation which is necessary to effect the sloughing or separation of the noxious dead matter from the living structure. We can see the utility of a similar treatment in other forms of external disease, where the inflammation is at once irritative and powerless.

We have already glanced at the treatment of our second order of irritations, that of excessive irritability, for the mixed manner of their occurrence renders it inexpedient to consider each kind quite separately from the other; but we return to the subject, in the endeavour, as far as is possible, to make this sketch of the principles of the treatment correspond with the preceding pathological history. Excessive irritability, as we have there remarked, most frequently depends on inflammation or some of the states akin to it, or (to use the more comprehensive words of M. Andral) hyperæmia in its several forms. In such cases relief is to be sought in the various antiphlogistic measures, applied of course with due relation to the organ whose morbid irritability is to be reduced; and thus evacuants, derivants, counter-irritants, and contro-stimulants, become remedies for irritation. These are considered in the article INFLAMMATION sufficiently to supersede notice here, further than the remark that their anti-irritant may not always be in the ratio of their antiphlogistic effects; and where irritation predominates over inflammation, those are to be preferred which act on the nervous as well as on the vascular functions; thus, counter-irritants (and if they be admitted as a separate class, contro-stimulants also) will avail more than mere vascular depletories in fulfilling the indication in view. For example, in the vehement irritations connected with slight phlogoses of the mucous membranes of the lungs and of the alimentary canal, (notwithstanding Broussais' positive assertions to the contrary,) tartar emetic frictions for the former, and sinapisms and blisters for the latter, are far more efficacious than local or general bloodletting. The irritations of serous membranes, which in persons of mobile sensibility frequently present the semblance, although they partake little of the real character, of inflammation, likewise receive most relief from this description of antiphlogistic treatment. The contro-stimulant or sedative influence of cold directly applied is exerted equally on the vessels and nerves, and it would be, doubtless, a powerful means of subduing irritations, were it a more manageable agent; as it is, we see its beneficial influence in the relief afforded to cerebral irritation, and in those of the limbs by applications of ice and cooling lotions. The expediency of using it, (as do the Broussaïans,) in abdominal and thoracic inflammatory irritations, is very questionable: the risks of repelling the inflammation more inwardly, and of its being aggravated by reaction if the application of cold is unsteady or insufficient, besides the obvious injury to the system of continually abstracting from organs that degree of heat which is almost

necessary to their life, are surely sufficient objections against a practice that is far from being generally recommended by the experience of its advocates. External heat, whether dry, as applied by hot flasks, bricks, or air, and acting as a rubefacient, or combined with moisture in fomentations, baths, or poultices, and proving revulsive and sudorific, is a much less exceptionable remedy for internal irritations. In its moderate degrees the latter are more suited to inflammations, as their effect is principally on the circulation, which they soothe and equalize; but in its highest tolerable degree, heat produces a strong impression on the nervous system; very hot flasks, or flannel wrung out of water almost scalding, are among the most powerful of antispasmodics or local anodynes, and we have seen them produce perfect and immediate relief in the irritative pains of colic and dysmenorrhœa, where many powerful narcotics had failed.

As we are now verging on the subject of means directed particularly to lower nervous irritability, we may premise that there are some narcotic or sedative remedies which, if they do not act as such on the vascular system likewise, do not stimulate it; they are, therefore, often admissible in inflammation itself, and are the more strongly indicated when it exhibits the character of nervous irritation. Of these, none for safety and general applicability ranks before the hyoscyamus. Mr. Travers says, "In the ruffled states of the system generally, but especially in the over-active state of the vascular system, there is a charm in the operation of henbane altogether peculiar. It is feeble as an anodyne, feeble as a soporific, but 'not poppy nor mandragora' soothe and still so unexceptionably as henbane." This remark, although true, requires a comment; the over-activity of the vascular system here alluded to is not one of inflammation, but of irritation, dependent on excess of nervous irritability scattered through the different organic sympathies; and it is in its sedative influence on these that the charm of henbane consists; for it exerts little or no effect on inflamed vessels, that are, as it were, over-active in their own strength. We may almost say that on its little interference with the vascular system its general eligibility depends; for, restraining no secretions, it can advantageously be given alone or combined, without the risk of purchasing temporary relief at the expense of that balance of functions which is so essential to health; and unless where pain and excited sympathies are useful as guides in the employment of more active remedies, there is scarcely an instance of morbid irritation unfitted for its use. The main fault of hyoscyamus is its weakness as a narcotic; it not unfrequently fails of its effect, and, perhaps sooner than other remedies of the same class, loses its power by continued use.

Of the other remedies of this class we may mention favourably conium, belladonna, colchicum, digitalis, and hydrocyanic acid. Their fitness in various diseases is less extended than that of the medicine already named; and it is

particularly restrained by their greater liability to disagree with the stomach. The two first approach in their properties most nearly to hyoscyamus. The three others exert a decidedly sedative effect on the vascular system, but rather through an influence on the heart, the force and number of whose pulsations they diminish, than from any action on the vessels at large. Their beneficial effect is, therefore, best seen in irritations of this organ and of the lungs, which stand in so close a relation to the heart. The directly sedative influence of hydrocyanic acid is, however, sometimes remarkably evinced by its allaying the morbid irritability of the stomach; and it is successfully applied externally to allay the irritation of prurient eruptions. Colchicum is supposed to possess a specific sedative power in the irritations of gout and rheumatism. Whether this may depend on its carrying off through the kidneys an irritant matter from the blood is uncertain; but the diuretic effect of this remedy and of digitalis should not be overlooked. Conium and belladonna, when the system can bear them in sufficient doses, are sometimes very beneficial in allaying irritation of the pulmonary system, whether manifesting itself in spasm of the bronchi, or in an excessive irritability of the mucous membrane, exciting cough. The smoke of stramonium and of tobacco enjoys a similar reputation, but it is decidedly stimulant to the vascular system. Poultices of the recent leaves of various narcotic herbs, but particularly conium and belladonna, are very efficient in allaying the irritation of unhealthy ulcers: the leaves of the latter in form of ointment shew great power over both vessels and nerves, in relieving and preventing the chordees of gonorrhœa.

We pass over others of lesser note to the chief of narcotics, opium. This medicine, although under certain circumstances the most sure and most powerful of anti-irritants, has so many ulterior effects, that more than any other it requires judgment in its exhibition. Its first effect is to stimulate the vascular system, and this is sufficient to exclude it from all those instances of sthenic inflammation where it is wished to retard or arrest rather than to hasten this process. But in the asthenic phlegmasiæ, especially where nervous irritation predominates, the administration of opium is counter-indicated only by the ulterior effects which it may have in arresting the secretions. Combined with ipecacuanha, with antimony, and especially with mercury, it ceases to be liable to this objection, and its operation is often in the highest degree salutary. Even where it is wanted as a pure anti-irritant, to reduce morbid sensibility in the nerves, we should always prefer it in combination with ipecacuanha, which seems to equalize without injuring its narcotic virtues; and in further combinations, it is not common to experience from this compound the inconveniences that frequently result from laudanum or opium. The muriate and acetate of morphia, equally with Battley's *liquor opii sedativus*, enjoy the reputation of a purer sedative property than the common forms of the

drug possess; but unless where a speedy effect is desired, there are few cases in which we would not place greater confidence in Dover's powder, or tantamount combinations of ipecacuanha and the aqueous extract of opium. It is an almost indispensable adjunct to purgatives in violent gastro-enteric irritation, where hyoscyamus would be insufficient; and if the stomach will retain it, it seldom fails to quell the excessive disturbance that sometimes follows drastic and unguarded purgation. In dysentery, and in more chronic forms of excessive irritability of the intestinal canal, the proportion of ipecacuanha may with advantage be doubled or quadrupled, as in the dose of one-fourth or one-eighth of a grain of extract of opium, with one-half or a whole grain of ipecacuanha, repeated according to the urgency of the symptoms.

We must notice a more obscure class of remedies, alteratives, which, whatever may be their mode of action, are unquestionably entitled to a place here. Under this unscientific but convenient title, we reckon the various non-purgative forms of mercury, whether simple or combined with opium, those of antimony and ipecacuanha in acute diseases, and in chronic disorders minuter doses of the same, sarsaparilla, mezereon, chalybeates, and a host of other medicines. The efficacy of the first named of these in restraining and subduing inflammatory action would obtain for them, among the disciples of the new Italian doctrine, the appellation of *contro-stimuli*; but this, like cutting the Gordian knot, is only substituting a bold stroke of hypothesis for a solution of the difficulty. It is not impossible that tartar-emetic and mercury may exert on the coats of inflamed or irritated vessels such an influence as directly neutralizes or subdues their disorder, and restores their healthy function; but this is a large assumption to take for granted; and in the absence of any sort of positive proof, we think it safer and as philosophical to arrange the remedies in question under the modest title of *alteratives*. These remedies are powerful in subduing irritation; and on the basis of the views which we have given of this morbid state, we might equally well frame an hypothesis that they act by restoring a lost balance, and by equalizing the distribution of natural irritability. But we will content ourselves with remarking the fact, that mercury, antimony, and in a minor degree ipecacuanha, tend moderately and equally to restore all the secretions which inflammation and irritation arrest or pervert; whilst opium, deprived in this combination of its restraining qualities, happily allays the excited sensibilities and sympathies of the nervous system. The alteratives prescribed in chronic irritations, although in greater variety, probably act on the same principle; and, perhaps, the exhibition of what are called alterative doses of blue pill, Plummer's pill, ipecacuanha, dandelion, and sarsaparilla, and mineral waters in chronic diseases of the viscera and skin, is more generally acknowledged as an appeal to the various secretions.

Before passing to the last class of remedies, tonics, we would advert for a moment to the salutary effect of friction and exercise in allaying morbid irritabilities of a part of the system. They hold an intermediate place between alteratives and tonics, and in affinity with either they well merit consideration. Friction, steadily and moderately applied, is an efficient anodyne. Although injurious in acute inflammations, it allays in a wonderful manner various nervous pains, spasms and other disagreeable sensations connected with irritation and irregular circulation, and it is a valuable auxiliary to anodyne applications. It is an alterative to the vascular system, inasmuch as it removes congestions and obstructions, and promotes healthy circulation and secretion; and in the regular continuance of these effects by exercise, increased by the contact of pure air, consists the tonic power of these hygeian agents.

The utility of tonics in subduing morbid irritabilities will, if we mistake not, be sufficiently apparent from the pathological views which we have endeavoured to expose. Agents which give tone and strength to the vascular system will destroy the preponderance of that nervous mobility which is the basis of irritation. Under their prosperous influence, disposition and power to act will go together, and within due bounds produce the harmonious balance of even health. Whether certain of them possess a specifically sedative property towards the nervous system, or whether this is their secondary effect after their tonic and astringent influence on the vessels, is beyond our means of decision; but the fact is not less ascertained than important, that the continued use of nitrate of silver or sulphate of copper will cure the epileptic irritations independent of organic cause, and often diminish them where the cause is irremovable, by lowering in the nerves their susceptibility to its impressions. Thus, likewise, bark, carbonate of iron, arsenic, sulphate of zinc, or subnitrate of bismuth, sometimes remove the painful or spasmodic irritations of tic douloureux, hemicrania, sciatica, chorea, and gastrodynia, which the most powerful anodynes, antispasmodics, and counter-irritants fail to affect. The stomach and intestinal canal, likewise, under the influence of a bitter tonic, will often lose various signs of irritation, which, however they may occasionally be accompanied by slight hyperemia or fancied inflammations, owe their being to weakness and want of tone. The cold shower or plunge bath or cold ablution is another efficacious tonic; the more eligible often, because, without loading the system with medicine, it rouses it to the exertion of its own powers in a vigorous vascular reaction, under the habit of which nervous mobility is physically forgotten and ceases. But it is needless to add to examples which have been adduced only as illustrations of a principle.

We have, finally, to glance at the leading peculiarities required in the treatment of indirect irritation, or that arising in the reaction after prostration. The most obvious indication is to promote and regulate the reaction, so that it

may rise to the point of a general and equal recovery of function, without passing beyond it into a state of irritation or inflammation. The most common state which we have to deal with is that of irregular reaction, local and misdirected excitement amidst general prostration. Whether this excitement consist in convulsion, hiccup, vomiting, delirium, palpitation, or cough, it is of the utmost importance that it should be subdued; and to effect this, it is of more avail to direct our efforts to excite the powers generally by diffusible stimuli than to attempt to quiet the local irritation by sedatives; for as the other powers rise from the prostration, this symptom will generally subside. But should this not be the case, and the local irritation be wearing down the strength, sedatives must be addressed to it; this part of the treatment will not differ from that of morbid irritability already considered. The point which characterizes the treatment of this form of disease is the necessity for counteracting the prostrating influence which paralyzes the plurality of the functions, leaving others in proportionate predominance. This indication resolves itself into the removal, as far as is possible, of this influence, and the further obviation of its effects.

Cold and the resulting prostration are removed by the same means, the gradual and cautious restoration of heat, beginning by frictions with snow, &c. and carefully restraining the disposition which is commonly manifested to excessive reaction; on this account diffusible stimuli are only sparingly admissible. See COLD.

The prostrating influence of a severe mechanical injury, as of a crushed limb or bad compound fracture, seldom ceases on the removal of the limb; on the contrary the additional shock of the operation not unfrequently proves fatal. The absence of inflammation leaves the system open to the noxious influence of the shattered structure, which inflicts a stroke felt even after its removal. Were healthy inflammation soon excited, this would probably in a degree counteract or interrupt this influence; and we hazard the suggestion that stimulating applications made to the injured part previously to the operation, might, as in extensive burns, be of more avail than mere internal stimuli. The existence of inflammation in the system has been shown by Dr. M. Hall to protect it in a remarkable degree against the prostrating effects of loss of blood, and the same thing obtains in some measure in other cases of prostration; hence asthenic inflammation may be useful not only as proving power in the system, but also as a general tonic, imparting a stimulus to the heart and vessels. This remark is most applicable to surgical cases, in which inflammation is an important and necessary process; but we see in it also an explanation of the utility of artificial inflammations excited by sinapisms, blisters, and stimulant frictions, in failure of the powers from various causes, and in the state of sinking from any severe disease. Any of these measures as local counter-irritants and

general stimulants often prove beneficial in arresting vomiting, hiccup, convulsions, or any other partial reaction amidst general prostration. In the worst cases, however, they fail to excite inflammation; for the skin, like other parts, seems to have lost the attributes of vitality.

Of the diffusible stimuli fit to oppose the state of sinking or prostration, the most powerful are ammonia, alcohol, and opium. These are variously applicable according to the degree to which the depression has extended. Ammonia is the most purely stimulant, and is, therefore, best adapted to cases in which there is least of local irritation, or where this manifests itself in spasms. The complete prostration induced by tobacco, digitalis, and other sedative poisons, and the asphyxia from the fumes of charcoal and sewers, are examples to which the stimulus of ammonia seems to be especially adapted. The carbonate of ammonia is the most common preparation, and it is conveniently combined with alcohol in the *spiritus ammoniæ aromaticus*, which is the form most agreeable to the stomach. It is to be borne in mind, however, that it is a chemical agent as well as a vital stimulant; and this circumstance precludes its being given to a very large amount. Spirit in the various combinations, brandy, wine, and ether, is a highly valuable stimulant; and it is the one perhaps most to be depended on in general prostration with irregular reaction. It exhibits some narcotic virtue in its property of quieting the irritated sympathies of this state, and is peculiarly serviceable in arresting the severe vomiting which often severely and fatally aggravates various forms of exhaustion. It is of the greatest importance to watch most assiduously the state of a patient who requires a large exhibition of stimuli of this kind, both to ensure their being supplied often enough, which in case of sinking must be done every five or ten minutes; and to diminish or withdraw them the moment they produce an effect on the circulation, lest they stimulate it beyond the point of moderate and general reaction into a state of febrile excitement. Opium, as it partakes largely of narcotic as well as of stimulant properties, is less adapted to the extremest forms of prostration than to those in which the irritability of the system is misdirected. In the state of sinking, when the respiratory function is failing with the rest, opium might have the effect of destroying the sensibilities and sympathies on which this vital process depends. But for the different partial irritations attendant on general weakness, particularly delirium, spasm, palpitation, and hiccup, opium is generally the most satisfactory remedy. Solid opium and its tincture are here the most expedient forms; and their stimulant effect is most fully developed by small doses frequently repeated. If the antispasmodic property is desired, larger quantities must be given; and it is truly astonishing what doses the system will bear when under the influence of spasmodic disease.

The first objects in extreme prostration are, to sustain the functions of respiration and cir-

ulation by diffusible stimuli, until there is a sufficient recovery of the forces to support these without further aid. The organic functions of secretion and assimilation then generally require some assistance; for the effects of the depressing influence sometimes manifest themselves on them after the circulation has been restored to some degree of vigour. Here alteratives and tonics come into requisition; and, as in direct irritation, they must be variously modified and combined in order to ensure the most equal and natural excitement of the several organic processes. Where the prostrating influence still remains in the system, counteracting vigorous reaction, and enfeebling or paralyzing all the conservative powers, these several remedies must be conjoined. Thus, under the noxious influence of gangrene, asthenic erysipelas, or poisoned wounds, it becomes necessary to administer wine or spirits, ammonia, opium, or camphor, with bark or sulphate of quinine, whilst the secretions are excited by calomel or blue pill. Bark has sometimes a signal power in combating with the depressing influences in question; and its efficacy may, perhaps, depend on the same property which renders it so complete an antidote to the causes of intermittent fevers.

The irritation of inanition, in respect to its symptoms, may require in great part the same treatment as that from other causes; thus sedatives to the nervous system, and the exclusion of all sensorial excitements, will be equally necessary. But the nature of the causes may modify the indications: as they consist in a loss from the system, the necessity of supplying nourishment for the reparation of that loss, giving to the assimilatory organs the aid of additional stimuli, is obvious.

It is necessary to be on our guard against the invitations which these forms of disease sometimes hold out for the use of antiphlogistic measures: these afford but temporary relief to the pseudo-inflammations which arise in this state, and which are more safely and effectually subdued by sedatives, a judicious supply of nourishment, and an exclusion of all exciting or disturbing agencies. Thus we may see a disease following extensive evacuations, which puts on the semblance of violent pleurisy, pericarditis, arachnitis, or hydrocephalus, often completely relieved by hyoscyamus or opium, with a sustaining nourishment, such as sago, arrow-root, or jelly, with small quantities of brandy or wine. The state of the circulation is the safest guide in the conduct of this treatment; as long as the pulse is weak or fluttering with its quickness, and although sharp or jarring in its first impulse, yet leaves the artery in the intervals empty under the finger, the sustaining treatment must be continued, and local pains, palpitation, disturbance of the mind with beating or noises in the head, viewed as partial reactions, to be subdued by opium or hyoscyamus rather than by the lancet and evacuations. But if these symptoms have been relieved, and the pulse has recovered in a measure its steadiness and fulness, the spirits and other stimuli must be diminished or withdrawn,

and the rest of the cure left to time and to whatever alteratives circumstances may suggest. These points are more fully described under the heads of the several diseases connected with this subject, and which have been already referred to.

The prophylactic treatment of those liable to irritations will generally consist of those means which, by giving tone to the vascular system, remove the preponderance of nervous influence or susceptibility. These are tonic medicines and a tonic regimen in general; but if there be already a loss of balance in the vascular system, it will be generally necessary to direct some alternative to regulate it. There are various circumstances of diet and regimen which tend greatly to engender a general morbid irritability; particularly an habitual and excessive indulgence in spirituous liquors, smoking, very strong tea or coffee, and opium-eating; close or crowded habitations, and a sedentary mode of life. Besides avoiding these predisposing causes, those who are of an irritable habit should rise early and keep regular hours, use exercise in a bracing air freely, but not so as to induce much fatigue, live on food of the most wholesome and nutritious kind, and attend in every possible way to the promotion of equality and regularity of the functions.

(C. J. B. Williams.)

ISCHURIA RENALIS.—The generic term ischuria has been employed not only by medical writers in general, but by professed nosologists, men of high reputation, to designate two very different affections. Thus by Sagar, ischuria has been defined "retention or suppression of urine secreted by the kidneys, or suppression of the secretion in the kidneys." Sauvages, in his definition, uses the term *retention*; Cullen that of *suppression* only. The first of the above-mentioned authors seems indeed to have recognized a distinction between the one and the other affection, though he has not laid it down with sufficient perspicuity. Sauvages and Cullen evidently regarded retention and suppression as equivalent terms; yet to distinguish them accurately is of great importance, and, in treating of the only species of ischuria which belongs to the province of the physician, it shall be our endeavour to avoid confusing the one with the other. We would tread in the steps of modern writers, eminent for the soundness of their views and justness of discrimination; of Dr. Good, among others, who has assigned to complete suppression of urine the appellation of "*paruria inops*," while to obstruction or retention of the secretion in the kidneys he has given the name of "*paruria retentionis renalis*." In accordance with his view of the subject, yet retaining the term ischuria as one more familiar to the medical world, we may speak of the former under the title of *ischuria renalis suppressionis*, and of the latter under that of *ischuria renalis retentionis*. Suppression or destitution of urine may occur as an idiopathic affection, or as the result of other local or general disease. The causes of idiopathic suppression are involved

in considerable obscurity; probably, however, they are to be sought for in some affection of the brain and nervous system, producing palsy of the kidneys, or in a congested state of the emulgent veins.

Cases of idiopathic suppression are certainly rare, though perhaps not so rare as some authors have imagined them to be. The affection may be described, sufficiently for every practical purpose, in very few words. In an individual, generally one of full habit, inclined to corpulency, and past the meridian of life, the secretion of the kidneys becomes suddenly and completely suspended; but as there has existed little or it may be no previous indisposition, as there is no provocation to pass water, no pain or sense of weight in the lumbar region, no fulness of the hypogastric region, or of any part of the abdomen, the patient probably disregards the suppression for several hours, till, being seized by a rigor, or experiencing an unusual degree of heaviness and oppression, he deems it prudent to resort to medical advice. The medical man finds his patient complaining of some nausea, and of torpidity of the whole system, and with a pulse somewhat slower than natural, yet still with so little pain and so free from distention or any other very distressing or urgent symptom, as to entertain no apprehension respecting the result himself, and to be regarded perhaps by his friends as fanciful and nervous. The catheter is employed, it passes freely into the bladder, but no urine follows. At this juncture, whatever may be the impression of the patient or his family, or of unscientific observers, the experienced practitioner will descry no small danger. His prognosis will be decidedly unfavourable. He is well aware that the constituent principles of the urine cannot long be retained in the blood without being productive of serious mischief. To save the patient, the kidneys must be roused to action, and that speedily; they must resume their functions, or their important office must be assumed by some other organ. Now to stimulate the palsied kidneys to action is by no means an easy task, and the remedial efforts of nature or the resources of art may prove too feeble or too tardy to compensate effectually for the destitution of the discharge from the kidneys. In a few hours vomiting and hiccup supervene, the torpor of the system increases, the brain especially is oppressed, and generally on or about the second or third day from the commencement of the suppression, the patient dies comatose, as in a state of apoplexy.

In some of these cases a strong urinous smell is perceptible before death, evidently proving that nature was endeavouring to convert the exhalents of the skin into a substitute for the palsied kidneys, but was not able completely to succeed.

Such, usually, is the rapid and fatal course of idiopathic suppression of urine, which, as has been already observed, is generally a disease of elderly people. Cases, however, are on record where the suppression continued for a much longer period without danger, and the

subjects of which were young persons or children. As a striking example of these chronic and less dangerous cases may be adduced one, copied from a foreign journal into the *Medico-Chirurgical Review* for April of the present year. The subject of this singular history was a boy, twelve years of age, who, it is stated, secreted no urine for seven weeks, though all that time he partook freely of liquids. The bowels acted naturally every second or third day; there was no increase of perspiration, but the contrary; the appetite was tolerable, the sleep sound; the boy was to all appearance healthy. It is added that there was no suspicion of deception either on the part of the patient or of his friends. At the end of the seven weeks, turpentine injections and frictions were employed, and balsam of copaiba was administered internally. Why these remedies were not had recourse to earlier is not explained; it would appear, however, that they had the effect of exciting the action of the kidneys in two days. To this certainly marvellous relation the able editor of the *Medico-Chirurgical Review* has subjoined one very similar, which fell under his own observation. In this latter case it was impossible deceit could be practised; the catheter was introduced almost every day, but a few drops of blood only followed. There was no affection of head, nor is any mention made of increased perspiration or of diarrhoea. Various other instances of complete suppression of urine, which subsisted for a long time, and were unattended with danger, are recorded by Dr. Parr, Dr. Richardson, &c. Nay, some cases have been mentioned where the affection has been coeval with the birth of the individual. May it not, however, be suspected that a more severely critical examination of such cases would have led to the discovery that *some* urine (a very small portion it might have been, but that *some* urine) was secreted and passed? We must always remember, as has been justly remarked by Sir Henry Hallford, that a very small measure of urine is sufficient for the exigencies of the constitution, and that it is the *total cessation* of the secretion that is so uniformly fatal.

Or, if it be conceded that in these cases not a drop of urine was passed by the natural channel, or discharged at any foreign outlet; if, in a word, it be conceded that no *urine* whatever was secreted, might not more accurate investigation have determined them to belong to the ischuria suppleta of Sauvages?

It may be proper in this place to say a few words respecting this latter variety of ischuria renalis, in which the want of the secretion in the kidneys is compensated by a vicarious discharge, as also of that variety in which urine itself is thrown off by some foreign outlet. Cases of either description are uncommon, and, among those which have been published, some perhaps have been simulated; yet a sufficient number, distinctly related, and by writers of good authority, remain to entitle the ischuria suppleta of Sauvages and the paruria erratica of Dr. Good to our consideration.

The more usual emunctories which take up the office of the kidneys, are the skin and bowels; and several well-authenticated histories are to be met with in which we are assured that while not a drop of urine was secreted in the kidneys, there were most profuse perspirations, or diarrhoea, to such an extent as would, under different circumstances, have reduced the patients to an alarming degree. Occasionally the system has been relieved by vomiting of a fluid resembling urine as to colour, but yet altogether devoid of urinous smell or taste. But one of the most singular cases of vicarious discharge is that quoted by Sennertus from Platerus, of a girl thirteen years of age, in whom the secretion of the kidneys was compensated by a very copious flow of serous fluid from the right ear, which continued during several days. The relation occurs in the *Medicina Practica* of Sennertus, lib. iii. cap. 10.

That the suppression of the proper secretion of the kidneys should sometimes be compensated by a vicarious discharge, or, in other words, a secretion of a different kind, may not appear very extraordinary or difficult to comprehend; but when we approach the subject of erratic urine, there is much which we are at a loss to explain. If we suppose the kidneys not to secrete at all, how or where are we to imagine the urine to be separated from the blood? If we adopt what seems the more probable conclusion, that in cases of *uroplania* the fluid is first secreted in the kidneys, and afterwards is re-absorbed by the increased activity of the urinary lymphatics, still how are we to account for its being carried to the salivary glands, to the stomach, to the axillæ, &c.?—how are we to explain the fact of its having been detected in the ventricles of the brain? By what path and in what manner is it conveyed to the foreign outlet or the remote situation?

In the treatment of idiopathic suppression of urine, we should bear in mind the great probability of its depending upon a congested state of the brain or of the vessels of the kidneys themselves; and, if the subject of the affection be a person of full habit, if the pulse be slow and full, if there be a considerable oppression of head, we should not hesitate to employ general bloodletting, and that freely; if the above-mentioned symptoms be less marked, and the patient less plethoric, cupping from the neighbourhood of the head or from the loins may be sufficient. The abstraction of blood should be promptly followed up by the exhibition of a brisk purgative, as calomel with the compound gamboge-pill, succeeded, if need be, by a saline cathartic draught. In the event of these or other purgative medicines being rejected, remedies of a similar description must be administered in the form of enema, as, for example, oil of turpentine with castor-oil.

Having premised these general remedies, our attention should be next directed to the kidneys more particularly. We should employ stimulating diuretics, as small doses of oil of turpentine or balsam of copaiba, repeating them at short intervals; or, should these medicines

prove offensive to the stomach, the tincture of cantharides, with spirit of nitric ether in camphor mixture, may be given. Of the rest of this class of remedies the most important, perhaps, are the infusion and spirit of horse-radish, squill, and spirit of juniper. Of the *pyrola umbellata* and certain other reputed diuretics, our experience is far too limited to enable us to speak with confidence; and in an affection so important, and generally so quickly fatal as idiopathic ischuria renalis, we should scarcely think of resorting to remedies so little known, while others of acknowledged efficacy are within our reach. *Digitalis* has been recommended; but the only form in which its diuretic powers can be depended upon is that of infusion; and where a great disposition to nausea exists, we should be cautious in advising its exhibition in that form. If *digitalis* be employed at all in the present disease, it should be in combination with spirit. *atheris nitrici*, *tinctura cantharidis*, spirit. *armorac. comp.*, or other stimulants.

Opium has been proposed, under the notion of spasm existing in the vessels of the kidneys. Under such a view we should not have recourse to it, but in its combination with some other medicines, as *ipecacuan* for example, it may prove useful; for in the treatment of the disease under consideration, we must ever recollect that the excretions of the skin may assist those of the kidneys, and that, therefore, it is an important part of our duty to endeavour to excite the former, by active diaphoretics, to take upon themselves for a time the office of the latter, and carry off the urea which should be discharged by the kidneys.

Before concluding this part of our subject, we must strongly insist upon the importance of external remedies; of these the principal are electricity and galvanism, blisters, cataplasms of mustard and horse-radish, and *terebinthinate* frictions. The hot-bath may also be employed, or the *sudatorium*; the use of the latter, followed up by a full dose of *Dover's* powder or other powerful diaphoretics, will seldom fail to excite profuse perspiration.

But suppression of urine may occur as a result of other local or general disease; and then, of course, it will be attended by several symptoms in addition to those which are observed in the idiopathic affection. Thus, when it arises in consequence of renal inflammation, there will necessarily be considerable pain and tenderness in the lumbar region, with other symptoms of *nephritis*, hereafter to be noticed when we come to speak of that disease more particularly. When it proceeds from transferred gout, there will also be severe pain in the loins; and when it is caused by calculus, there will be weight and dull pain. Suppression of urine may also take place at the commencement of inflammatory fever. In all these cases our remedial measures must be directed to overcome the original disease. In proportion to the intensity and duration of the latter, will be the degree and duration of the suppression: with the cessation of the primary disease the suppression will cease.

Suppression of urine sometimes occurs towards the fatal termination of certain diseases. Under such circumstances nothing can be done.

Retention of urine in the kidneys.—We have now briefly to notice retention of urine in the kidneys. In this, as in the affection we have just been considering, there is no flow of urine; but in other respects it differs materially from suppression. In suppression the kidneys no longer secrete; in retention the secretions are not inactive, but the secreted fluid is obstructed in its passage. The obstruction may arise from a variety of causes. It may arise from spasm, from inflammation, abscess, or scirrhus of the kidneys; from hydatids, from calculous concretions, grumous blood, or viscid mucus in them; or from spasm or inflammation of the ureters; from calculi or other matters filling up their cavities; from their obliteration in consequence of ulceration; from tumours pressing upon them. The urine, though secreted in sufficient abundance, may be prevented from flowing into the pelvis of the kidney, or from thence into the bladder, by great enlargement of the gland. The same effect may also be produced by considerable extenuation of the kidney. Under this latter circumstance, though a small portion of urine may still be separated from the blood, yet, as the sinus of the organ contracts with its body, not a single drop may be able to pass into the ureter.

In most, if not in all, of the cases above mentioned, there will be dull pain, or a sensation of weight and uneasiness in the loins; and sometimes, as, for example, when the kidneys are greatly enlarged, there will be a fulness perceptible to the touch, or even to the eye; generally, however, owing to the peculiar situation of those organs, no intumescence is to be detected.

Complete renal retention is a very serious disease, inasmuch as it rarely takes place unless either both kidneys are simultaneously obstructed, or, one having previously been rendered incapable of performing its functions, the other, which had done double duty, becomes completely obstructed. It is not a common occurrence for both kidneys to be simultaneously affected; and in cases of absolute retention we may therefore conclude, or at least we may strongly suspect, that one of those glands has for some time been useless, or that one ureter has been impervious. Still, however, we must recollect that fatal retention has occasionally happened, though one kidney and its ureter have been wholly free from disease. For this we can account in no other manner than by supposing that the sound kidney is affected by sympathy; the irritation

produced by calculous concretions or other causes in the one organ may excite spasm in the other.

In the management of renal retention of urine we must be regulated by the cause, so far as we are able to ascertain it. Thus, if from the accompanying fever, and the violence of the pain, we judge it to arise from inflammation, we must employ general or topical bleeding, followed by mild aperients, and relaxants, and anodynes. If it appear to depend on calculus, mild aperients and relaxants may be all that the case demands; but here also, if there be considerable pain, venesection must not be neglected; and after venesection recourse must be had to anodynes. If the retention be in consequence of enlargement or hypertrophy of the kidney without evidence of inflammation, we are not to expect much from medicine. If both kidneys be thus affected, the case may indeed be regarded as hopeless. If one only be enlarged, the other probably will, for a time, take upon itself the whole duty; and a cure of the diseased organ may be attempted by the persevering exhibition of small doses of mercury, and the application of the emplastrum ammoniaci cum hydrargyro to the lumbar region. The well-known power of iodine in promoting absorption would point it out as an appropriate remedy in this state of disease: it may be employed in the form of its tincture; the dose being at first five or six minims, which may be gradually and cautiously increased to twenty minims or more,* three times a day; or the ointment of iodine, or of hydriodate of potass, may be rubbed in twice a day over the region of the enlarged gland.

If from the course of the pain, and the sense of weight, together with numbness of either lower extremity, and retraction of testicle, we suspect the obstruction to exist in the ureters, the only remedies from which we are to expect relief are relaxants and opiates. In this variety the retention is very rarely complete, for it is extremely uncommon for both ureters to be obstructed at the same time, or, when one is obstructed, for the other to be so affected by sympathy as to offer a total impediment to the flow of urine.

(H. W. Carter.)

ITCH.—See SCABIES.

* The words, *or more*, are added because we know much larger doses have been given, and, it is said, with impunity. Our own experience, however, is against large doses of that powerful medicine. Our astonishment has been very great on reading the treatment of a case of epilepsy by Dr. Franklin of New York, who, it seems, gave *one hundred drops* thrice a day for a month. See *Lancet* for July 30, p. 554.
